Summary
Cells require ribonucleotide reductase (RNR) activity for DNA replication. In bacteria, electrons can flow from NADPH to RNR by either a thioredoxin-reductase- or a glutathione-reductase-dependent route. Yeast and plants artificially lacking thioredoxin reductases exhibit a slow-growth phenotype, suggesting glutathione-reductase-dependent routes are poor at supporting DNA replication in these organisms. We have studied proliferation of thioredoxin-reductase-1 (Txnrd1)-deficient hepatocytes in mice. During development and regeneration, normal mice and mice having Txnrd1-deficient hepatocytes exhibited similar liver growth rates. Proportions of hepatocytes that immunostained for PCNA, phosphohistone H3 or incorporated BrdU were also similar, indicating livers of either genotype had similar levels of proliferative, S and M phase hepatocytes, respectively. Replication was blocked by hydroxyurea, confirming that RNR activity was required by Txnrd1-deficient hepatocytes. Regenerative thymidine incorporation was similar in normal and Txnrd1-deficient livers, further indicating that DNA synthesis was unaffected. Using genetic chimeras in which a fluorescently marked subset of hepatocytes was Txnrd1-deficient while others were not, we found that the multigenerational contributions of both hepatocyte types to development and to liver regeneration were indistinguishable. We conclude that, in mouse hepatocytes, a Txnrd1-independent route for the supply of electrons to RNR can fully support DNA replication and normal proliferative growth.

Key words: Ribonucleotide reductase, Liver regeneration, Partial hepatectomy, DNA precursors, Cell cycle, Replication, Proliferation

Introduction
Conversion of ribonucleotides into deoxyribonucleotides by ribonucleotide reductase (RNR) is essential for genomic DNA replication (Arner and Eriksson, 1995; Holmgren, 1981; Nicander and Reichard, 1983; Thelander and Reichard, 1979). Thioredoxin was first discovered as a source of electrons for RNR in E. coli (Laurent et al., 1964) and thioredoxin reductase was identified as the flavin-containing enzyme that used electrons from NADPH to restore the redox state of oxidized thioredoxin (Moore et al., 1964). Subsequent studies showed that a glutathione-reductase-dependent source of electrons could also support RNR activity and DNA replication. In this pathway, glutathione reductase transfers electrons from NADPH to glutathione, glutathione reduces glutaredoxin, and glutaredoxin donates the electrons to RNR (Holmgren, 1976; Miranda-Vizuete et al., 1994; Miranda-Vizuete et al., 1996).

Similar to bacteria, yeast and plants can survive in the absence of a functional thioredoxin-thioredoxin reductase pathway by using the glutathione-reductase-dependent source of electrons to fuel RNR (Koc et al., 2006; Meyer et al., 2009; Reichheld et al., 2007). Biochemical studies showed that mammalian RNR can also obtain electrons from the glutathione-reductase-dependent pathway (Luthman et al., 1979; Luthman and Holmgren, 1982) and a recent kinetic study showed that either route supports similar RNR enzymatic efficiency in vitro (Avval and Holmgren, 2009). Thus, it appears that most life forms might be able to use either thioredoxin reductase- or glutathione-reductase-dependent pathways to drive RNR-dependent DNA precursor production. However, none of the mammalian biochemical systems used to date have been able to approach the rate of RNR activity that would be required to support S phase replication in vivo (Avval and Holmgren, 2009), and the effectiveness of either source is not necessarily equivalent in all species (Arner, 2009; Fernandes and Holmgren, 2004).

Although the electrons supplied to RNR by either the thioredoxin reductase- or the glutathione-reductase-dependent route can support DNA replication, eukaryotic systems studied to date tended to favor the thioredoxin-reductase-dependent pathway (Arner, 2009; Arner and Holmgren, 2006a; Berndt et al., 2007; Lu and Holmgren, 2009). For example, yeast lacking thioredoxins exhibit a reduced rate of proliferation, skewed deoxyribonucleotide pools, and a protracted S phase, consistent with the glutathione-reductase-dependent pathway being a poor provider of DNA precursors (Koc et al., 2006). Measurements of the in vivo redox state of RNR
verified that thioredoxin is normally the major direct provider of electrons for RNR in yeast (Camier et al., 2007). Similarly, plants lacking thioredoxin reductases show a slow-growth phenotype that is consistent with compromised replication (Reichheld et al., 2007).

The biological world contains two known families of thioredoxin reductase enzymes (Arner, 2009). One, a smaller protein with high substrate fidelity for thioredoxin, is found in Archaea, eubacteria, plants, protists and fungi. The other is a larger enzyme that evolved independently from glutathione reductase, has higher substrate promiscuity, and has been found universally in metazoan animals (Aleksunes and Manautou, 2007; Arner, 2009; Lobanov et al., 2009; Lu and Holmgren, 2009; Meyer et al., 2009). It remains unclear why an ancestral pre-metazoan animal might have discarded its thioredoxin reductase genes (both cytoplasmic and mitochondrial forms of the enzyme) and generated a new lower fidelity family of enzymes from glutathione reductase; however, this event might underlie fundamental differences in the thioredoxin-reductase-pathway functions between animals and other life forms.

Previous studies suggested that, like yeast and plants, metazoans might also preferentially use their thioredoxin-reductase-dependent pathway to fuel RNR. Thus, although mice lacking glutathione reductase are viable (Rogers et al., 2004), mice lacking thioredoxin 1 (Txn1) (Matsui et al., 1996) or thioredoxin reductase 1 (Txnrd1) (Bondareva et al., 2007; Jakupoglu et al., 2005) are embryonic lethal. Lethality, however, does not necessarily implicate an RNR activity deficiency. Txn1 also participates in reducing protein disulfides and supplying electrons to homeostatic and antioxidant systems, including peroxiredoxins, methionine sulfone reductases and others (Arner, 2009; Fomenko et al., 2009; Kim and Gladyshev, 2007; Rundlof and Arner, 2004). We recently showed that disruption of Txnrd1 in mouse hepatocytes or fibroblasts results in chronic induction of cytoprotective pathways, which are thought to compensate for the loss of Txnrd1 in homeostatic antioxidant functions (Suvorova et al., 2009). Embryonic lethality in Txnrd1-deficient mouse embryos occurs only after replication has generated several thousand (Bondareva et al., 2007) or more (Jakupoglu et al., 2005) Txnrd1-deficient cells, again suggesting that functions other than DNA precursor production underlie lethality. Similarly, disruption of the genes encoding either mitochondrial thioredoxin (Txn2) (Noff et al., 2003) or mitochondrial thioredoxin reductase (Txnrd2) (Conrad et al., 2004) are also embryonic lethal despite these proteins being generally located in a compartment (mitochondria) separate from that of ribonucleotide reduction for genomic DNA replication (cytosol) (Arner, 2009).

Our recent analyses of mice having hepatocyte-specific disruption of the Txnrd1 gene showed strikingly normal liver development, including apparently normal levels of endoreplication and acetykinetic mitosis in mature Txnrd1-deficient hepatocytes (Suvorova et al., 2009). Also, although RNAi knockdown of Txnrd1 in mouse cancer cell cultures inhibits self-sufficient growth and other cancer-related characteristics of the cells, it does not block proliferation (Yoo et al., 2006; Yoo et al., 2007). These studies could not rule out the possibility that replication was supported by Txnrd1 enzyme remaining from maternal (Bondareva et al., 2007; Jakupoglu et al., 2005), pre-hepatocytic (Suvorova et al., 2009) or residual (Yoo et al., 2006; Yoo et al., 2007) sources; however, they provided the first in vivo evidence to suggest that Txnrd1-deficient mammalian cells might be able to undergo genome replication. To determine if this was, indeed, true, we evaluated the requirement of Txnrd1 for replication in hepatocytes.

In the current study, we tested whether hepatocytes in mouse liver were able to proliferate in the absence of Txnrd1. Experimental systems were designed in which cells had been Txnrd1-deficient for extended periods and, in some cases, for many cell cycles, to rule out any possibility that persisting pre-formed Txnrd1 supported replication. Results showed that Txnrd1–/– hepatocytes were able to proliferate and, unlike proliferation in Txnrd-deficient yeast or plants (Koc et al., 2006; Reichheld et al., 2007), hepatocyte proliferative indexes were not measurably affected by loss of Txnrd1. Our results indicate that the Txnrd1-independent route supplying electrons for RNR can support normal replication in a mammalian system. The implications of this finding should be considered in therapies using drugs that inhibit or otherwise affect Txnrd1 activity.

Several different abbreviations are currently used for thioredoxin reductases, including Txnrd1, TxnR, TR and TRR. We have used the abbreviations for mouse enzymes recommended by the National Center for Biotechnology Information (NCBI) and the Mouse Genome Informatics database.

Genetic designations used in this paper are as follows. Gene loci are italicized and separated by a semicolon. Alleles are designated as superscript and separated by a slash. Transgenes are followed by a superscript to indicate whether they are homozygous present (\(^{1}\)), hemizygous (\(^{0}\)) or absent (\(0^{0}\)). For example, \(\text{Txnrd}1^{1/-};\text{AlbCre}^{0}\) is heterozygous for a null (\(-\)) allele of \(\text{Txnrd}1\) and does not carry an \(\text{AlbCre}\) transgene.

**Results**

**Txnrd1-deficient hepatocyte populations expand and replicate DNA during liver development**

We previously established a mouse (\(\text{Mus musculus}\), strain C57Bl/6J) system in which all differentiated hepatocytes lack Txnrd1 (Suvorova et al., 2009). Briefly, female animals that are homozygous for the functionally wild-type yet Cre-inactivatable (‘conditional’) \(\text{Txnrd}1^{\text{cond}}\) allele (Bondareva et al., 2007) and for a two-color Cre-responsive reporter gene, \(\text{ROSA}^{\text{TmG}}\) (Muzumdar et al., 2007) (genotype \(\text{Txnrd}1^{\text{cond/cond}};\text{ROSA}^{\text{AmTmG/mTmG}}\)) were mated with males that were heterozygous for the null allele of \(\text{Txnrd1}\) (Bondareva et al., 2007) and carried two copies of an albumin promoter/enhancer-driven Cre transgene (Postic et al., 1999) (genotype \(\text{Txnrd}1^{1/-};\text{AlbCre}^{0}\)). Offspring were either \(\text{Txnrd}1^{\text{cond/-};\text{ROSA}^{\text{AmTmG}};\text{AlbCre}^{1}}\) (hereafter referred to as experimental) or \(\text{Txnrd}1^{\text{cond/-};\text{ROSA}^{\text{AmTmG}};\text{AlbCre}^{1}\text{(control)}\). The \(\text{AlbCre}\) transgene drives Cre expression in all differentiated hepatocytes (Postic and Magnuson, 2000; Postic et al., 1999) including those that arise in fetal stages (Weisend et al., 2009). The \(\text{ROSA}^{\text{TmG}}\) allele, in its non-recombined state, drives strong membrane-targeted accumulation of the red fluorescent protein tdTomato in all cell types (Muzumdar et al., 2007). Exposure to Cre deletes the tdTomato cistron and uncovers a cistron that yields a membrane-associated modified green fluorescent protein (GFP).

Thus, in experimental animals, all cells are \(\text{Txnrd}1^{\text{cond/-}}\) and red fluorescent, except differentiated hepatocytes, which are \(\text{Txnrd}1^{1/-}\) and green fluorescent (Suvorova et al., 2009). Previous studies showed that livers from these mice expressed almost no functional Txnrd1 mRNA or protein, suggesting all hepatocytes completely lacked Txnrd1 (Suvorova et al., 2009). In control animals all cells are red fluorescent and \(\text{Txnrd}1^{\text{cond/-}}\) except differentiated hepatocytes, which are green-fluorescent and \(\text{Txnrd}1^{1/-}\) (Suvorova et al., 2009). In these studies as well as in previous studies, we have been unable to measure a difference in phenotype between...
Contributions of Txnrd1-deficient hepatocytes versus Txnrd1-containing progenitor cells to liver regeneration

To induce global proliferation of differentiated hepatocytes, we performed partial hepatectomies on adult mice. Following surgical removal of two-thirds of normal rodent liver, most differentiated hepatocytes rapidly enter the cell cycle and proliferate to regenerate liver mass (Higgins and Anderson, 1931; Martins et al., 2008; Mitchell and Willenbring, 2008; Watanabe, 1970). DNA synthesis peaks around 36 hours post-hepatectomy as the first semi-synchronous wave of hepatocytes transits S phase, and proliferation remains elevated until regeneration is complete, after 7-10 days (Mitchell and Willenbring, 2008). At hepatectomy, experimental liver masses were ~24% greater than control liver masses; rates of liver mass accumulation following a two-thirds hepatectomy were similar in experimental and control mice (Fig. 3A), suggesting that Txnrd1-deficient livers were not compromised in regenerative tissue growth.

Fig. 1. Hepatocyte-specific allelic conversion in mouse liver by AlbCre. (A) Low-magnification micrograph showing merged fluorescence and DAPI staining of a cryosection of liver from an adult (P42) mouse of genotype AlbCre1/txnrd14cond/cond; ROSAmT-mG/+; ROSA+/–. All hepatocytes in this image, identified as large and generally cuboidal cells with abundant cytoplasm with large heterogeneous weakly DAPI-stained nuclei, and frequently having two nuclei or oversized polyploid nuclei, have green fluorescent membranes, which indicates that AlbCre1 efficiently directed Cre-mediated allelic conversion in hepatocytes. All non-hepatocyte cells, in particular the endothelial cells, identified as very small irregularly shaped cells with small strongly DAPI-stained nuclei, form tubular networks surrounding blood vessels and capillaries, exhibited red fluorescence. Note that the intensity of red fluorescence in non-hepatocyte cell nuclei did not vary similarly, the peri-venous zones appear darker and redder. We are uncertain of the causes of this hepatocyte-specific zonal fluorescence variation, although it might reflect zonal differences in metabolic activity of hepatocytes resulting from natural gradients in oxygen tension or nutrient availability. Careful examination revealed that nearly all hepatocytes in all zones had exclusively green membranes. (B) High-magnification fluorescent micrographs of a DAPI-stained liver cryosection from an aged adult (P280) animal of genotype P280; AlbCre1/txnrd14cond/cond; ROSA+/–. The red channel (left) shows endothelial membranes surrounding capillaries. The green channel (middle) shows hepatocyte membranes. The merged channel (right) shows that hepatocyte-endothelial interfaces have both red and green membranes (white arrows), whereas hepatocyte-hepatocyte interfaces have only green membranes (yellow arrows). Scale bars: 50 μm.
Liver growth can occur by either proliferation of differentiated hepatocytes or proliferation of pre-hepatocytic progenitor cells followed by differentiation into hepatocytes (Oertel and Shafritz, 1999; Weisend et al., 2009). Because allelic conversion was driven by AlbCre, which is induced coincident with hepatocyte differentiation (Postic et al., 1999; Weisend et al., 2009), proliferating progenitor cells would contain Txnrd1. To distinguish contributions of Txnrd1-containing pre-hepatocytic progenitor cells from proliferation of Txnrd1-deficient differentiated hepatocytes, we developed a novel ‘ten-day chronometer’ of hepatocyte lineage age based on conversion of the ROSAmT-mG allele by AlbCre (S. V. Iverson, K.M.C., C.M.W., J.A.K. and E.E.S., unpublished data). Briefly, activation of the AlbCre transgene during hepatocyte differentiation (Postic et al., 1999; Weisend et al., 2009) will simultaneously convert both the Txnrd1cond allele and the ROSAmT-mG allele (Suvorova et al., 2009; Weisend et al., 2009). Cre-mediated recombination of ROSAmT-mG initiates a progressive conversion in membrane fluorescence from red to green as GFP accumulates and tdTomato protein decays. Fluorescent marker conversion in hepatocyte membranes required roughly 10 days to complete (Muzumdar et al., 2007) and data not shown. Therefore, 48 hours after partial hepatectomy, hepatocytes arising from pre-hepatocytic progenitor cells (0- to 48-hours post-onset of Cre expression) will exhibit low ratios of green/red fluorescence and could be readily distinguished from the purely green hepatocytes arising from proliferation of preexisting hepatocytes. At this time point, nearly all hepatocyte membranes exhibited purely green fluorescence (Fig. 3B). At low incidences, fields of view in some peri-portal regions could be found with newly differentiated hepatocytes (i.e. retaining some red membrane fluorescence; Fig. 3C, orange arrows denote younger (redder) hepatocytes than the light-green arrows), verifying that contributions of progenitor cells to liver regeneration could be detected using this system. Importantly, frequencies of newly differentiated hepatocytes were low during regeneration (~1% of total hepatocytes) and did not differ significantly between experimental and control livers (Fig. 3C,D). Most hepatocytes 2 days after partial hepatectomy arose from cell lineages that had differentiated into hepatocytes prior to hepatocyte; pre-hepatocytic progenitor cells were only minor contributors.

Thioredoxin-deficient yeast are able to proliferate; however they exhibit a protracted S phase and a prolonged cell cycle (Koc et al., 2006). Static frequencies of S phase hepatocytes cannot, alone, indicate either differences in cell cycle duration or in S phase duration; however, by measuring multiple static proliferative indexes representing different cell cycle phases, one can more accurately determine whether the cell cycle is perturbed (supplementary material Fig. S1). To test whether disruption of Txnrd1 in hepatocytes affected cell cycle progression, we measured the proliferative index by PCNA staining, the S phase index by BrdU labeling, and the M phase index by staining for PHH3 (Fig. 4A). Results showed no measurable differences in any of these proliferative indexes between hepatocytes within regenerating control and experimental livers (Fig. 4B).

Based on previous studies in lower eukaryotes (Koc et al., 2006; Reichheld et al., 2007), it was surprising that mouse hepatocyte proliferation was not measurably affected by disruption of Txnrd1. As a control, we confirmed that the RNR inhibitor hydroxyurea entirely prevented regenerative replication of both normal and Txnrd1-deficient hepatocytes (Fig. 5A). Also, in vivo post-hepatectomy metabolic labeling showed that thymidine incorporation during liver regeneration did not differ between normal and Txnrd1-deficient livers (Fig. 5B). In combination, the data above show that proliferative liver growth was driven primarily by hepatocyte proliferation, not by proliferation of Txnrd1-containing progenitor cells, and they indicate that the ability of RNR to support hepatocyte DNA replication was not measurably compromised by disruption of Txnrd1.

**Contributions of Txnrd1-containing versus Txnrd1-deficient cell lineages to development and regeneration of genetically chimeric livers**

For a potentially more sensitive comparison of relative proliferative potentials, we generated fetally induced genetically chimeric mice in which individual livers contained both red-fluorescent-tagged
normal and green-fluorescent-tagged Txnrd1-deficient hepatocytes. Using these mice, we evaluated the contributions of both hepatocyte types to developmental and regenerative liver growth. By this approach, the size of the adult liver can be seen as a target niche that the two types of hepatocytes will compete to populate. This results in a ‘multi-generational relay-race’ in which cells with a subtle genetic growth advantage will pass this advantage to their daughter cells, thus amplifying the proliferative difference each generation. To produce the mosaics, we used the Tamoxifen-inducible ROSACreER allele (Badea et al., 2003). Dams of genotype Txnrd1cond/cond;ROSAmT-mG/mT-mG were mated to sires of genotype Txnrd1cond/cond;ROSACreER/CreER. In this mating, the dams themselves lack the ROSACreER allele and do not exhibit Cre activity in response to Tamoxifen; however, all progeny are genotype Txnrd1cond.cond;ROSAmT-mGat0/Gat0 so that fetal cells exposed to Tamoxifen can convert to Txnrd1−/− and from red to green fluorescence. A time and dose study established that intraperitoneal (IP) administration of 0.5 mg of 4-hydroxytamoxifen (4OHT) to pregnant dams at embryonic day 14.5 (E14.5) resulted in 100% survival of pups to term (C.M.W., J.A.K. and E.E.S., unpublished data). By this dosage protocol, pups uniformly exhibited 30-50% green (Txnrd1−/−) hepatocytes as neonates (Fig. 6A and not shown), whereas frequencies of green cells in other organs were much lower (ranging from a low of <0.1% in brain to a high of ~10% in pancreas, with most organs ~1%; C.M.W. and E.E.S., unpublished data).

Following maternal administration of 4OHT at E14.5, cryosections of livers harvested from neonatal [postnatal day (P) 6], juvenile (P14-P28), young adult (P35) and older adult (P102) offspring showed similar mosaic distributions of ~50-70% red...
Fig. 4. Proliferation of Txnrd1-deficient hepatocytes during liver regeneration. (A) Proliferative marker staining in post-hepatectomy livers. Adult (P42) mice of genotypes Txnrd1cond/–; AlbCre1–/– (left panels, controls) or Txnrd1cond/+; AlbCre1–/– (right panels, experimentals) were two-thirds hepatectomized. For PCNA (upper panels) and PHH3 (middle panels) staining, livers were harvested 48 hours post-hepatectomy when the first ‘wave’ of proliferative hepatocytes would be around G2-M in the cell cycle. The abundant hepatocytes with diffuse cytoplasmic PCNA staining (upper panel) are presumably in M or early G1 phase, after nuclear membrane dissolution allows PCNA protein to redistribute into the cytoplasm. Hepatocytes with nuclear or cytoplasmic staining were scored as proliferative, as both types are either within or just exiting from a proliferative cell cycle. PCNA-positive cell counts in liver 36 hours post-hepatectomy were similar (not shown) albeit with less cytoplasmic staining. For BrdU staining (lower panels, experimentals) were two-thirds hepatectomized. After 35 hours of recovery, mice received a single IP inoculation of either HU in saline (lower panels; + HU) or saline alone (upper panels; – HU). This was followed 30 minutes later with an injection of BrdU + HU (lower panels) or BrdU alone (upper panels). After a 1-hour labeling period, livers were harvested. Regardless of genotype, no BrdU-positive cells were detected in HU-treated animals. Scale bars: 100 μm in all panels. (B) Proliferative indexes for resting (pre-hepatectomy; pre) or regenerating (post-hepatectomy; post) liver. N.D., not determined. Values are means and s.e.m. for counts on three animals. Statistical analysis indicated that none of the differences between control and experimental samples was significant.

Although a portion of this is accounted for by the increase in average liver cell size that occurs during rodent development (–fivefold during post-natal development in rats (Schmidt and Schibler, 1995)), we estimate that there is also a 30- to 100-fold developmental increase in the number of hepatocyte genomes in mice, which accounts for the majority of this growth. This increase in hepatocyte genomes, in the absence of any cell death, would require five to seven consecutive cell doublings ($2^{5} \equiv 32; 2^{7} \equiv 128$). Since relative representation of both the E14.5-converted Txnrd1–/– (green) and the non-converted Txnrd1cond/cond (red) hepatocytes was similar in mosaic juvenile and adult livers (Fig. 6A,B), we concluded that, by adulthood the cell lineages leading to both hepatocyte types had undergone a minimum of five to seven consecutive replicative cycles since their Cre-mediated genetic divergence without showing a measurable difference in proliferative potential.

Fig. 5. Sensitivity to hydroxyurea and [3H]thymidine incorporation during regeneration of control and Txnrd1-deficient livers. (A) RNR requirement for replication. Adult (P42) mice of genotypes Txnrd1cond/–; AlbCre1–/– (left panels, controls) or Txnrd1cond/+; AlbCre1–/– (right panels, experimentals) were two-thirds hepatectomized. After 35 hours of recovery, mice received a single IP inoculation of either HU in saline (lower panels; + HU) or saline alone (upper panels; – HU). This was followed 30 minutes later with an injection of BrdU + HU (lower panels) or BrdU alone (upper panels). After a 1-hour labeling period, livers were harvested. Regardless of genotype, no BrdU-positive cells were detected in HU-treated animals. Scale bars: 100 μm. (B) Quantitative thymidine incorporation. Mice of the same genotypes and ages as in A were two-thirds hepatectomized and, 33 hours later, received 12.5 μCi of [3H]thymidine IP. Livers were harvested 6 hours later and the specific activity of nuclear acid-precipitated DNA was determined using 0, 0.1, 0.3 and 1.0 mg nucleic-acid equivalents of nuclei. Values for all animals were plotted and best-fit lines for each genotype were assigned by least squares regression.

(normal) and ~30-50% green (Txnrd1-deficient) hepatocytes (Fig. 6A), indicating that Txnrd1-containing hepatocytes did not have a growth advantage over Txnrd1-deficient hepatocytes despite having 5 days of pre-natal and 102 days of post-natal development to manifest a competitive advantage. At P14 and P22, when liver is predominantly composed of hepatocytes (Weisend et al., 2009) yet hepatocytes had completed, we quantified the cellular dynamics of liver development. Fresh whole livers harvested from E14.5 fetal mice from our colony weighed 0.0315±0.0032 g (mean ± s.e.m., n=6). Previously, we showed that E14.5 liver is composed of <10% differentiated hepatocytes by mass (Weisend et al., 2009). In adults, the liver weighs ~1.6 g (Fig. 3A) and is composed of ~95% differentiated hepatocytes by mass (Schmidt and Schibler, 1995; Weisend et al., 2009). Thus, there is a roughly 500-fold increase in mass of total liver hepatocytes during development.
Discussion

Txnrd1 disruption, selenium assimilation, and the hepatocyte selenoproteome

Mammalian Txnrd s are selenoproteins, meaning they contain the atypical amino acid selenocysteine (Sec) (Gladyshev and Hatfield, 1999; Lobanov et al., 2009; Lu and Holmgren, 2009). Only 25 mammalian selenoproteins are known or predicted, all of which are oxidoreductases and all of which have Sec participating in active site electron transfer (Fomenko et al., 2007; Lobanov et al., 2009; Lu and Holmgren, 2009). Production of Sec, selenide is either acquired from organic dietary sources or as inorganic selenide and selenite. Dietary selenite is reduced to selenide by either the glutathione reductase (Gsr)-reduced glutathione-glutaredoxin or the Txnrd-Txn systems, whereas the mechanisms of selenate reduction remain uncertain (Lu et al., 2009; Lu and Holmgren, 2009). We have not tested whether disruption of Txnrd1 has global effects on the selenoproteome within individual cells, although the apparent redundancy of sources and reductase systems for mobilization of dietary selenium suggests Sec availability would not become limiting in Txnrd1-deficient cells.

Alternative pathways of supplying electrons to RNR

In all life forms studied to date, RNR activity is essential for DNA replication. RNR activity, in turn, is dependent on a source of electrons. Genetic malleability of bacterial, yeast and plant systems allowed identification of both thioredoxins and glutaredoxins as the electron donors for RNR in these systems; thioredoxins and glutaredoxins ultimately obtain the electrons from NADPH via thioredoxin reductase or via glutathione reductase and glutathione, respectively (Avval and Holmgren, 2009; Meyer et al., 2009).
Previously, it had not been possible to test the relative contributions of these two pathways in vivo in mammals. It has long been known that mammalian glutaredoxin can provide electrons to RNR in vitro (Luthman et al., 1979; Luthman and Holmgren, 1982) and a recent study showed that both Txn1 and glutaredoxin are similarly efficient at supplying electrons to RNR in vitro (Avval and Holmgren, 2009). None of these biochemical assays could approach rates of deoxyribonucleotide production required during S phase, however, and no previous study definitively established that mammalian cells could replicate DNA and proliferate in the absence of Txnrd1. The survival and relatively normal physiology of mice lacking Gsr indicates that the Gsr-dependent pathway is not necessary in mammals (Rogers et al., 2004). Conversely, embryonic lethality of mice lacking either Txn1 (Matsui et al., 1996) or Txnrd1 (Bondareva et al., 2007; Jakupoglu et al., 2005) indicates that some aspect of the Txnrd1-dependent pathway is essential in mammals.

Although mice having a disrupted Txnrd1-Txn1 system are not viable, several lines of evidence suggested Txnrd1 is not essential for cell proliferation. First, cells in Txnrd1-deficient mouse embryos underwent at least twelve consecutive doublings prior to embryonic arrest (Bondareva et al., 2007; Jakupoglu et al., 2005). Second, knockdown of Txnrd1 in cell cultures did not affect cell proliferation (Yoo et al., 2006; Yoo et al., 2007). Third, mice lacking Txnrd1 in all differentiated hepatocytes have normal or slightly larger than normal sized livers (Fig. 3A) (Suvorova et al., 2009). It was possible that proliferation in these systems used cryptic sources of Txnrd1 (i.e. maternally derived in embryos, progenitor cell-derived in hepatocytes or residual following knockdown). Alternatively, a Txnrd1-independent pathway might have been supporting replication.

The most obvious alternative pathway for supporting RNR activity in Txnrd1-deficient hepatocytes would be the Gsr-dependent system that has been described in other eukaryotes and activity in Txnrd1-deficient hepatocytes would be the Gsr-dependent pathway that has been described in other eukaryotes and activity in Txnrd1-deficient hepatocytes would be the Gsr-dependent pathway (Arner, 2009; Arner and Holmgren, 2006a). Txnrd1 has been extolled as a ‘drugable target’ for cancer therapies (Arner, 2009; Arner and Holmgren, 2006a; Rundlof and Arner, 2004), suggesting Txnrd1 activity supports cancer growth and progression (Arner, 2009; Arner and Holmgren, 2006a). Considerable attention has been given to possible roles for Txnrd1, both favorable and deleterious, in cancer initiation and progression (Arner, 2009). Whereas Txnrd1 activity is thought to protect against the initiation of cancers (Arner, 2009; Arner and Holmgren, 2006b; Ganther, 1999), many aggressive cancers exhibit increased expression of Txnrd1 (Berggren et al., 1996; Nakamura et al., 2000; Rundlof and Arner, 2004), suggesting Txnrd1 activity supports cancer growth and progression (Arner, 2009; Arner and Holmgren, 2006a). Txnrd1 has been extolled as a ‘drugable target’ for cancer therapies (Arner, 2009; Arner and Holmgren, 2006a; Bindoli et al., 2009; Gandin et al., 2009). Numerous cancer drugs or drug candidates affect Txnrd1 activity, either as a primary target or, as in the case of cisplatin and other platinum-containing compounds (Sasada et al., 1999; Witte et al., 2005), as a collateral target. Some of these include arsenic trioxide (Lu et al., 2007), various organo-gold compounds (Bindoli et al., 2009; Casini et al., 2009; Coronnello et al., 2005; Gandin et al., 2009; Marzano et al., 2007; Rigobello et al., 2009), some mercury-containing compounds (Carvalho et al., 2008), and certain quinols (Chew et al., 2008),

implications for Txnrd- and Txn-targeted pharmaceuticals

In addition to providing electrons to RNR, the Txnrd1-Txn1 system is a major protein thiol reductase; it provides reducing potential to enzymes including peroxiredoxins and methionine sulfoxide reductase, and it is generally considered to be a major participant in cellular antioxidant defense and redox regulation (Arner, 2009; Arner and Holmgren, 2006a; Meyer et al., 2009). We previously showed that disruption of Txnrd1 in embryos or hepatocytes resulted in a strong cytoprotective response, including induction of drug metabolism genes and upregulation the Nr2 stress-response pathway (Bondareva et al., 2007; Suvorova et al., 2009). It is unclear how these responses might compensate for loss of Txnrd1 in cells. However, in the mutant livers where biochemical analyses could be performed, we observed no evidence of oxidative stress, suggesting this response was, indeed, compensatory (Suvorova et al., 2009). We are aware of no evidence that any of the cytoprotective pathways induced in Txnrd1-deficient hepatocytes could directly supply electrons to RNR.

In addition to providing electrons to RNR, the Txnrd1-Txn1 system is a major protein thiol reductase; it provides reducing potential to enzymes including peroxiredoxins and methionine sulfoxide reductase, and it is generally considered to be a major participant in cellular antioxidant defense and redox regulation (Arner, 2009; Arner and Holmgren, 2006a; Meyer et al., 2009). We are aware of no evidence that any of the cytoprotective pathways induced in Txnrd1-deficient hepatocytes could directly supply electrons to RNR.

Implications for Txnrd- and Txn-targeted pharmaceuticals

Considerable attention has been given to possible roles for Txnrd1, both favorable and deleterious, in cancer initiation and progression (Arner, 2009). Whereas Txnrd1 activity is thought to protect against the initiation of cancers (Arner, 2009; Arner and Holmgren, 2006b; Ganther, 1999), many aggressive cancers exhibit increased expression of Txnrd1 (Berggren et al., 1996; Nakamura et al., 2000; Rundlof and Arner, 2004), suggesting Txnrd1 activity supports cancer growth and progression (Arner, 2009; Arner and Holmgren, 2006a). Txnrd1 has been extolled as a ‘drugable target’ for cancer therapies (Arner, 2009; Arner and Holmgren, 2006a; Bindoli et al., 2009; Gandin et al., 2009). Numerous cancer drugs or drug candidates affect Txnrd1 activity, either as a primary target or, as in the case of cisplatin and other platinum-containing compounds (Sasada et al., 1999; Witte et al., 2005), as a collateral target. Some of these include arsenic trioxide (Lu et al., 2007), various organo-gold compounds (Bindoli et al., 2009; Casini et al., 2009; Coronnello et al., 2005; Gandin et al., 2009; Marzano et al., 2007; Rigobello et al., 2009), some mercury-containing compounds (Carvalho et al., 2008), and certain quinols (Chew et al., 2008),

The conditional hepatocyte-specific Txnrd1-deficient system provided a model in which prolonged temporal separation of gene disruption and proliferation could be achieved in vivo, thus eliminating the possibility that persistent pre-formed Txnrd1 was supporting replication. In the current study, we used this system to show that disruption of Txnrd1 had no measurable effect on the proliferative potential of hepatocytes in mice. Our results, combined with the normal physiology of Gsr-null mice (Rogers et al., 2004), lead us to conclude that, similar other life forms, animal cells can probably proliferate using either Txnrd- or Gsr-derived electrons to fuel RNR. Moreover, unlike yeast (Camier et al., 2007; Koc et al., 2006) and perhaps plants (Reichheld et al., 2007), we detected no evidence that the Txnrd1-dependent system was a preferential source of electrons. It is possible that this difference between species relates to the distinct evolutionary origins of metazoan compared with other eukaryotic thioredoxin reductases. Further studies will be required to distinguish the possible respective roles of Gsr versus cytosolic forms of Txnrd2 in supporting replication; however, intriguingly, the transcriptomes of both Txnrd1-deficient embryos (Bondareva et al., 2007) and livers (Suvorova et al., 2009) do not show any compensatory upregulation of mRNAs encoding either Gsr or Txnrd2. Thus, whatever pathway is supporting RNR activity during hepatocyte replication it might be sufficiently abundant and robust to fully support genomic DNA replication without further induction, and thus might be a major, as opposed to an alternative or compensatory, source of reducing potential for RNR. Although there might be some cell types or circumstances with different requirements, we find that either the Txnrd1-dependent or Txnrd1-independent route is probably equivalent in terms of supporting physiological RNR activity in hepatocytes.

Other roles and functions of the Txnrd1-Txn1 system

In addition to providing electrons to RNR, the Txnrd1-Txn1 system is a major protein thiol reductase; it provides reducing potential to enzymes including peroxiredoxins and methionine sulfoxide reductase, and it is generally considered to be a major participant in cellular antioxidant defense and redox regulation (Arner, 2009; Arner and Holmgren, 2006a; Meyer et al., 2009). We previously showed that disruption of Txnrd1 in embryos or hepatocytes resulted in a strong cytoprotective response, including induction of drug metabolism genes and upregulation the Nr2 stress-response pathway (Bondareva et al., 2007; Suvorova et al., 2009). It is unclear how these responses might compensate for loss of Txnrd1 in cells. However, in the mutant livers where biochemical analyses could be performed, we observed no evidence of oxidative stress, suggesting this response was, indeed, compensatory (Suvorova et al., 2009). We are aware of no evidence that any of the cytoprotective pathways induced in Txnrd1-deficient hepatocytes could directly supply electrons to RNR.

administered drugs in unexpected ways.

One class of anti-cancer drug whose activity might have been expected to be downstream of the Tnxr1-Tnxr1 pathway is the RNR inhibitors, such as hydroxyurea (HU). Prior to the current study, it seemed likely that Tnxr1 would be a crucial supplier of electrons for RNR in mammalian systems, and therefore, that inhibition of Tnxr1 might also affect RNR activity. We show that genetic elimination of Tnxr1 has no measurable effect on RNR-dependent hepatocyte proliferation. This suggests that the anti-cancer effects of Tnxr1 inhibitors are not the result of preventing Tnxr1 from supplying electrons to RNR. Instead, these effects are probably the result of either inhibiting other activities of Tnxr1 or of interactions of these electrophilic compounds with cellular targets other than Tnxr1. Thus, in strategic design of combination therapies, these Tnxr1 inhibitors would not be redundant with RNR inhibitors and might, in some cases, be synergistic with them.

Materials and Methods
Mice and animal care

All animal procedures were approved by the Montana State University Institutional Animal Care and Use Committee (MSU-IACUC). All renewable resources in this study are available on request for unrestricted non-profit research unless regulated by another party. All mice were housed with specialized care conditions including sterilized feed, water and bedding in HEPA-filtered forced-air cages (Tecniplast) under a 14 hour:10 hour light:dark cycle. Feed (PicoLab mouse diet 5058, which contains selenium) served as a natural component of the grains and supplemented to 0.33 p.p.m. with selenium selenite and were water-restricted. All mutant alleles were followed by PCR analyses of genomic DNA samples using the primers and conditions described previously (Bondareva et al., 2007; Suvorova et al., 2009; Weisend et al., 2009). Mouse tissues (Gt(ROSA)26Sortm1(cre/Esr1)Nat (here abbreviated ’ROSACreER’) (Badea et al., 2003), B6.Cg-Tg(Alb-Cre)21Mmg/J (’AlbCre’) (Postic et al., 1999), and C57Bl/6J were obtained from the Jackson Laboratory (stock numbers 007576, 004847, 003574 and 000664, respectively) and were maintained in our colony by back-crossing to C57Bl/6J. Mouse lines bearing the Tnxr1 and Tnxr1<sup>tm4</sup> alleles have been described previously (Bondareva et al., 2007), as have all hybrids between these lines that were used in the current study (Suvorova et al., 2009). Timed pregnancies were monitored by checking for vaginal seminal plugs each morning; noon on the day that a plug was found was defined as embryonic day 0.5 (E0.5). 4HHT (Sigma) was prepared as described previously (Badea et al., 2003) and was administered as an IP injection at the times and doses indicated in figures and legends.

Partial heptatectomies were performed as described previously (Mitchell and Willenbring, 2008) to remove the median and lateral lobes, which constitute approximately two-thirds of the mass of the liver. BrdU, when used, was administered as an IP injection of 50 mg/kg in sterile saline at the times indicated in figures and legends. To test the requirements of RNR for replication, HU was administered by another party. All mice were housed with specialized care conditions including sterilized feed, water and bedding in HEPA-filtered forced-air cages (Tecniplast) by another party. All mice were housed with specialized care conditions including sterilized feed, water and bedding in HEPA-filtered forced-air cages (Tecniplast)

Histology, microscopy, and image adjustments

Samples for cryosections were harvested into OCT compound (Tissue-Tek), frozen, and stored at −80°C; samples for paraffin embedding were harvested fresh into 10% neutral-buffered formalin. Processing and sectioning were performed by standard procedures as described previously (Bondareva et al., 2007; Suvorova et al., 2009; Weisend et al., 2009). Primary antibodies used for immunostaining were mouse-anti-

PCNA monoclonal antibody (Abcam, no. A1029), rabbit-anti-PHH3 (Cell Signaling Technologies, no. 9701), and mouse-anti-Brdu (Miltenyi Biotec) or rabbit-anti-DU monoclonal antibody (Sigma, no. B2531). Secondary antibodies were all horseshadish peroxidase conjugates, and were goat-anti-mouse (Pierce, no. 31430) or goat-anti-rabbit (GIBCO, no. 13859.012). All immunostaining was performed as per the suppliers’ recommendations and our previously reported protocols (Suvorova et al., 2009). Labeling indexes were assessed by counting total hepatocytes and labeled hepatocytes in arbitrary fields of view. In general, counts were continued until at least 30 labeled hepatocytes were tallied (e.g. 30,000 cells counted for a 0.1% labeling index, 100 cells counted for a 0.1% labeling index). Morphologically non-hepatocytic cells were not included in counts. Counting newly differentiated hepatocytes (Fig. 3C) was confirmed by monitoring the heterogeneity of hepatocytes and labeling of these cells in liver (Fig. 3B) and by their low overall abundance. Arbitrary fields of view were counted until at least 30 red hepatocytes were tabulated and a minimum of 10 fields had been evaluated, or until a maximum of 30 fields had been evaluated. By these criteria, newly differentiated hepatocytes in resting adult (pre-hepatocyte samples) were determined to represent <0.1% of hepatocytes in these conditions (Fig. 3C).

All cmyo and paraffin sections were cut 5.0 μm thick. Following immunostaining, paraffin sections for bright-field microscopy were counter-stained with Hematoxylin. Cryosections for fluorescence microscopy were counterstained using Fluoromount-G (Southern Biotechnology API (Southern Biotechnology Associates)). Primary antibodies were used for immunostaining were mouse-anti-

concentrations from three different animals from each genotype) was counted for four 1-minute periods by liquid scintillation counting. Counts per minute values for each sample were averaged and the average background (scintillation fluid only, no input nuclei) was subtracted. Data were plotted and a best-fit line was assigned by least-squares regression; line fit was evaluated by the coefficient of determination, $r^2$. Slope represents thymidine incorporation per input nucleus.

The authors thank S. Iversen, J. Prigge and G. Callis for their technical contributions or scientific criticisms of this work; we thank C. O’Rourke for training us to perform partial hepatectomies. M.F.R. was supported in part by a research scholarship from University Scholars Program at Montana State University; D.M.v.H. was supported by the Howard Hughes Medical Institute’s Undergraduate Research Program; K.M.C. was supported by the National Science Foundation’s Research Experiences for Undergraduates program; E.E.S. and C.M.W. were supported in part by the Montana Agricultural Experiment Station; infrastructure support came from NIH COBRE grant 2P20 RR021815 to VMB; other support was provided by Montana State University and by grants from the NIH and NSF to E.E.S. Deposited in PMC for release after 12 months.
