Lepton universality violation from neutral pion decays in $R_{K^{(*)}}$ measurements

Dean J. Robinson

$^{1}$Ernest Orlando Lawrence Berkeley National Laboratory, University of California, Berkeley, CA 94720, USA

I show that the neutral pion decay in $B \to K^{(*)}\pi^{0}\gamma$, with $\pi^{0}\to\ell\ell\gamma$, might generate large sources of lepton flavor universality violation (LFUV) in measurements of the ratios, $R_{K^{(*)}}$: If the photons in the $K^{(*)}\ell\ell\gamma$ final state are reconstructed as Bremsstrahlung, the recovered electron-positron invariant mass can be pushed into the 1–6 GeV$^2$ region, artificially enhancing the measured $B\to K^{(*)}\ell\ell$ branching ratio compared to $B\to K^{(*)}\mu\mu$. I present a conservative estimate and simulation of the $B\to K\pi^{0}\gamma$ LFUV background at LHCb, that together suggest this effect could reduce the recovered $R_{K}$ up to several percent. A reliable assessment of the size of this effect will require dedicated simulations within experimental frameworks themselves.

I. INTRODUCTION

Measurements of lepton flavor universality violation (LFUV) involving charged dilepton final states are long-known to exhibit LFUV from virtual photon poles. In a generic semi-leptonic process $X \to (\gamma^* \to \ell\ell')Y$, the branching ratio of light versus heavier lepton pair production is enhanced whenever the virtual photon momentum, $q$, falls below the pair-production threshold of the heavier pair, because of the $1/q^2$ pole from the virtual photon exchange in the amplitude. In the context of $R_{K^{(*)}}$ measurements, in which the LFUV ratio

$$R_{K^{(*)}} = \frac{Br[B \to K^{(*)}\mu\mu]}{Br[B \to K^{(*)}\ell\ell]}$$

the virtual photon exchange in $B \to K^{(*)}\ell\ell$ leads to significant LFUV in $R_{K^{(*)}}$ if $q^2 \ll 4m_{\ell}^2$.

Another effect of this type can arise in $R_{K^{(*)}}$ from $B \to \eta'K^{(*)}$, with the subsequent Dalitz decay $\eta' \to \ell\ell\gamma$ (see e.g. Ref. [1]). The photon pole in the $\eta'$ decay leads to a factor of 4 enhancement of the $\eta' \to \ell\ell\gamma$ branching ratio versus $\eta' \to \mu\mu\gamma$: $Br[\eta' \to \ell\ell\gamma] = 4.9(27) \times 10^{-4}$ versus $Br[\eta' \to \mu\mu\gamma] = 1.13(28) \times 10^{-4}$ [2]. This $B \to (\eta' \to \ell\ell')K^{(*)}$ cascade may then enhance the measured $B \to K^{(*)}\ell\ell$ branching ratio, whenever the final state photon is close enough to the electron or positron to be misreconstructed as Bremsstrahlung, or soft enough to be missed. At LHCb in particular, the relatively large boost of the $\eta'$ system suggests one could naively expect an $O(1)$ fraction of such photons to look like Bremsstrahlung: Noting the branching ratio $Br[B \to \eta'K] = 7.04(25) \times 10^{-5}$, this $B \to \eta'K$ LFUV background is known to lead to a percent level correction to $R_{K}$ [1]. For this background, however, the misreconstructed dilepton invariant mass, $q_{\text{reco}}^2 \approx m_{\ell}\gamma^2 < 1 \text{ GeV}^2$, and therefore it is only relevant to the signal region with dilepton invariant mass $q^2 < 1 \text{ GeV}^2$. In the signal region $1 < q^2 < 6 \text{ GeV}^2$, LHCb has recently measured $R_{K^{*}}=0.846^{+0.044}_{-0.041}$ [3, 4] (see also the very recent Ref. [5]), in notable tension with the SM prediction $1.00 \pm 0.01$ [1, 6, 7] (cf. Ref. [8]).

In this note, I point out that $b \to s\gamma$ final states involving neutral pion Dalitz decays may produce an additional significant SM source of LFUV in $R_{K^{(*)}}$ measurements. This has not been considered—or at least, not mentioned—as a systematic uncertainty in prior LHCb [3–5, 9, 10], Belle [11–13] or BaBar [14] analyses. In particular, I focus on the $B \to K(\pi^{0} \to \ell\ell\gamma)\gamma$ LFUV background at LHCb, as a representative of a possibly broader class of decays with the following pathology: The photon produced by the $b \to s\gamma$ transition could, on rare occasion, be reconstructed into the $\pi^{0}$ daughter electron or positron as Bremsstrahlung, so that the misreconstructed $q^2$ of the electron-positron pair may be pushed up into the $1 < q^2 < 6 \text{ GeV}^2$ signal region. This enhances the measured branching fraction for $B \to K\ell\ell$ in the signal region and thus reduces $R_{K}$. A schematic of the misreconstruction configuration of the $\pi^{0}$ decay is shown in Fig. 1, in which both photons reconstruct as Bremsstrahlung, creating a LFUV background. Other $b \to s\ell$ transitions might also contribute similarly to $R_{K}$, including $B \to Kh^{0}\gamma$ for any neutral (pseudo)scalar meson $h^{0} = \eta, \eta', \ldots$, as well as modes such as $B \to K\pi^{0}\pi^{0}\gamma$. The same effect may occur in $R_{K^{*}}$ measurements.

The $e^{+}e^{-}\gamma$ invariant mass could be measured precise enough at LHCb—nominally at $O(10\text{ MeV})$ uncertainty [15]—to reconstruct the $\pi^{0}$, providing a handle to reject this background. However, combinatoric challenges plus related studies with merged photons [16] suggest this cannot be done with the high efficiencies required, especially in the case that the daughter photon of the $\pi^{0}$ may itself be reconstructed as Bremsstrahlung or is soft enough to be lost. Because

![FIG. 1. Schematic configuration of $B \to K(\pi^{0} \to \ell\ell\gamma)\gamma$, with both photons misreconstructed as Bremsstrahlung.](image-url)
the neutral pion is highly boosted at LHCb, the former scenario itself is not expected to be rare—we show below it occurs for approximately half of the relevant \( \pi^0 \) decays—while the latter scenario is infrequent.

How big could such a LFUV background for \( R_K \) be? Naively, one expects the leading contribution to \( B \rightarrow K \pi^0 \gamma \) from the resonant channel \( B \rightarrow K^* \gamma \). Since \( \text{Br}[B^+ \rightarrow (K^{*+} \rightarrow K^+ \pi^0)\gamma] \approx 1/3 \times 3.92(22) \times 10^{-5} \) and \( \text{Br}[\pi^0 \rightarrow ee\gamma] = 1.174(35) \times 10^{-2} \) [2], the branching ratio for \( B \rightarrow K ee\gamma \) is comparable to that of \( B \rightarrow K ee \), a comparable reduction arises in the recovered \( R_K^{ee\gamma} \), comparable to the tension with the SM seen at LHCb.

In this note I explore how to estimate the size of this effect, and then develop an approximate simulation based on a rough, but conservative, guesswork for the implementation of the LHCb upstream Bremsstrahlung recovery algorithm. This simulation suggests an LFUV background present up to the several percent level in \( R_K \) from \( B \rightarrow K \pi^0 \gamma \) alone, but of course subject to sizeable uncertainties inherent to such approximations.

### II. DIFFERENTIAL BRANCHING RATIO

#### A. \( B \rightarrow K \pi^0 \gamma \)

To estimate the branching ratio for \( B \rightarrow K(\pi^0 \rightarrow ee\gamma)\gamma \), one must first determine the \( B \rightarrow K \pi^0 \gamma \) amplitude. To do so, since we are interested only in an estimate, I approximate this amplitude by the resonant contributions from the vector meson exchange, \( B \rightarrow (V \rightarrow K \pi^0) \gamma \), in which \( V \) is any strange vector meson with the appropriate \( J^P = 1^- \) quantum numbers. The first few such known mesons are shown in Table I.

| Meson (V) | Mass [GeV] | Width [GeV] | \( \text{Br}[B^+ \rightarrow V^+ \gamma] \) | \( \text{Br}[V \rightarrow K \pi^0] \) |
|-----------|------------|-------------|---------------------------------|--------------------------------|
| \( K^* \) | 0.8917(2)  | 0.0514(8)   | 3.92(22) \times 10^{-5} \pm 1/3 |                                |
| \( K^{*(1410)} \) | 1.414(15)  | 0.232(21)   | 2.7(6) \times 10^{-5} \pm 2(4)% |                                |
| \( K^{*(1680)} \) | 1.718(18)  | 0.322(110)  | 6.5(17) \times 10^{-5} \pm 12(8)% |                                |

TABLE I. Data for strange vector mesons with \( J^P = 1^- \) [2]. Isospin is assumed to determine \( K \pi^+ \) versus \( K \pi^0 \) branching ratios.

Apart from \( B \rightarrow K(\pi^0 \rightarrow ee\gamma)\gamma \), the \( K ee\gamma \) final state may also be accessed from the virtual photon/Z process \( B \rightarrow K(\pi^0 \rightarrow \gamma)^*(\gamma^*/Z^* \rightarrow ee) \). These contributions may be of comparable size, but the interference between them is expected to be negligible, because in the former the \( ee\gamma \) invariant mass is constrained to the narrow \( \pi^0 \) resonance, while in the latter this constraint applies to the diphoton mass. Thus we shall consider only the \( B \rightarrow K(\pi^0 \rightarrow ee\gamma)\gamma \) cascade, keeping in mind that our final result will likely be an underestimate of the full \( B \rightarrow K \pi^0 \gamma \rightarrow K ee\gamma \) rate. From the most conservative
perspective, because the photons in $\pi^0 \rightarrow \gamma\gamma$ must have the same helicity, the virtual $\gamma^*Z^*$ contribution cannot interfere with the contribution from $B \rightarrow K(\pi^0 \rightarrow ee\gamma)\gamma$ that has opposite helicity photons, which accounts for half the total rate. Thus, if there happened to be fully destructive interference, it would at most reduce our estimate by a factor of two.

The differential rate for $\pi^0 \rightarrow ee\gamma$, neglecting subleading radiative corrections in this discussion,

$$\frac{d\Gamma[\pi \rightarrow ee\gamma]}{d\cos\theta_e ds'} = \frac{\alpha s' - 4m^2\pi (m^2_e - s')^3}{512\pi^2 f^2 m^2\pi s'^{5/2}} \times \left[ s' (\cos 2\theta_e + 3) + 8m^2_e \sin^2\theta_e \right],$$

in which $f$ is the effective decay constant of the $(\pi/f)\bar{F}F$ operator, $s' \in [4m^2_e, m^2_\pi]$ is the electron-positron invariant mass, and $\theta_e$ is the helicity angle defined in Fig. 2. Straightforward integration of the differential rate (4) allows one to determine the total rate, and hence the normalized $\pi \rightarrow ee\gamma$ rate ($1/\Gamma$)$d\Gamma/d\cos\theta_e ds'$.

In the full cascade $B \rightarrow (V \rightarrow K(\pi^0 \rightarrow ee\gamma))\gamma$, taking the narrow width approximation for the $\pi^0$ resonance, the full differential branching ratio is then composed as

$$\frac{d\text{Br}[B \rightarrow (V \rightarrow K(\pi^0 \rightarrow ee\gamma))\gamma]}{d\cos\theta_K ds' d\cos\theta_e ds'} = \frac{d\text{Br}[B \rightarrow (V \rightarrow K(\pi^0 \rightarrow ee\gamma))\gamma]}{d\cos\theta_K ds' d\cos\theta_e ds'} \frac{\text{Br}[\pi \rightarrow ee\gamma]}{\Gamma[\pi \rightarrow ee\gamma]} \frac{d\Gamma[\pi \rightarrow ee\gamma]}{d\cos\theta_e ds' ds'}.$$

When combined with Eqs. (2) and (4), one may then determine the appropriate differential branching ratio weight of any kinematic configuration in the full cascade.

### III. SIMULATION

The goal is to simulate the differential distribution of the (mis)reconstructed dilepton invariant mass $q^2_{\text{reco}}$, while imposing appropriate cuts and requirements for the two photons to reconstruct as Bremsstrahlung in the lab frame. This can be defined equivalently as

$$q^2_{\text{reco}} = (p_B - p_K)^2 = m^2_B + m^2_K - \frac{E_K (m^2_B + s) + 2m_B |p_K| |k_\gamma| \cos\theta_K}{\sqrt{s}},$$

with $E_K$ the energy of the kaon in the $V$ rest frame.

I simulate the $q^2_{\text{reco}}$ differential distribution via a combination of unweighted Monte Carlo (MC) samples, as described below, and differential reweighting. In particular, with the exception of the $B$ boost distribution and the $K\pi$ invariant mass, $s$, a pure phase sample of the full cascade is created, and then reweighted according to the differential branching ratio weight (5). The reweighted sample is then binned according to the desired observable—i.e. $q^2_{\text{reco}}$—imposing lab frame reconstruction or cut requirements.

### A. $B$ boost and $K\pi$ resonances

Simulation of lab frame observables requires sampling the $B$ meson boost distribution in the LHCb acceptance, against which the differential weights from Eq. (5) must be composed. Simulation of $B$ meson production is done with *Pythia 8*, enforcing $p_T \geq 5$ GeV and requiring the pseudorapidity $2 \leq \eta \leq 5$. The resulting $B$ boost distribution of the simulated sample is shown in Fig. 3. The mean boost in this sample is $\langle \beta\gamma \rangle \approx 20.5$, which is very close to quoted averages [17].

From the data in Table I, the square amplitude $|F(s)|^2$ is shown in Fig. 4. When further normalized against $K^*$ resonance contribution, the integral $\int ds |F(s)|^2 / \pi \approx 1.95 \times \text{Br}[B \rightarrow K^{*}\gamma] \times \text{Br}[K^* \rightarrow K\pi^0]$, so that approximately half of the contribution to the branching ratio comes from the two higher resonances. Rather than reweighting from a uniform distribution in $s$, the reasonably sharp peak at the $K^*$ resonance makes it more efficient to create an unweighted sample of the distribution of the $K\pi$ invariant mass, $s$. For this purpose I create a sample of 10^5 events.
FIG. 5. Schematic for upstream Bremsstrahlung recovery at LHCb. Adapted with permission from Ref. [20], as reproduced in Fig. 4.4 of Ref. [19].

B. Bremsstrahlung Recovery

The details of Bremsstrahlung photon recovery within the LHCb analysis framework are not available to those external to the collaboration. One may find, however, approximate or rough details provided in various conference notes and public theses. For instance, Ref. [18] provides a (possibly somewhat dated) study of the recovery of radiation lost by leptons in \( B \to J/\psi(\epsilon\epsilon)K \). Figure 4.4 of Ref. [19] (as reproduced from Ref. [20]; see also Fig. 1 of Ref. [18]), from which Fig. 5 is adapted, provides perhaps the clearest visual clue to the Bremsstrahlung recovery: Photons whose deposit into the ECAL lies within the extrapolated angular deflection of a lepton track as it bends from the LHCb VELO through the TT to the magnet—the bending of an upstream or a long track—are considered compatible with upstream Bremsstrahlung. The precise region over which photon emission is considered compatible with upstream Bremsstrahlung is not specified in available literature, but instead characterized as the region ‘before the magnet’ \[18, 19\], or before the ‘region with sizeable magnetic field’ \[21\].

The differential angular deflection of a lepton track

\[
d\theta_{\text{def}} \approx 0.3 \times \left[ \int \frac{B dl}{\text{TTm}} \right] \left[ \frac{\text{GeV}}{p_\perp} \right],
\]

over differential path length \( dl \), with \( p_\perp \) the lepton momentum perpendicular to the magnetic field. Although outside the LHCb magnet the magnetic field diverges, I assume for simplicity that it is uniformly oriented in the \( y \) direction, with varying strength in \( z \) (using standard beam-axis coordinates; see Fig. 5). From the VELO to the front face of the TT, the bending power is measured to be \( \int B dl \approx 0.11 \text{Tm} \) \[22\], increasing to approximately 0.25 Tm at its back face, and approximately 0.33 Tm once the magnetic field has reached 0.5 T; half its full strength. To be conservative, I use \( \int B dl \approx 0.1 \text{Tm} \) in the estimate of the total angular displacement \( \theta_{\text{def}} \). In addition, I also show results for 0.3 Tm, representing a plausible scenario for the allowed upstream Bremsstrahlung emission region.

This very approximate understanding leads to the following approximate algorithm for simulation of a photon as Bremsstrahlung, shown in Fig 5: (i) For each lepton track, I construct a cone of angular size \( \theta_{\text{def}} \) around its truth lab frame momentum, \( p_\epsilon \); (ii) Because electrons (positrons) bend in the \(+x\) (\(-x\)) direction, I further divide the cone in the \( y-z \) plane and select the half-cone on the \(+x\) (\(-x\)) side, corresponding to the direction of the lepton angular deflection; (iii) Any photon that lies within this half-cone is considered compatible with recovery as an upstream Bremsstrahlung photon; Finally, (iv), as done in Refs. \[3–5, 9, 10\], I require a minimum transverse momentum, \( p_T \), threshold for the leptons. The precise threshold is not provided in the recent LHCb \( R_{K^+} \) analyses, however Ref. \[10\] specifies

\[
\min[p_T(e^+,p_T(e^-))] > 0.5 \text{ GeV},
\]

which appears compatible with Figs. S2 of Ref. \[4\]. The ECAL itself further has a finite resolution, that sets a lower bound for \( \theta_{\text{def}} \). Details of the ECAL cell resolution are hard to glean from available literature: To be conservative I assume perfect ECAL resolution, and compare this to setting a lower bound \( \theta_{\text{def}} > 5 \times 10^{-3} \), based on the ~5 cm size of an inner or middle ECAL cell \[23, 24\] at ~12 m from the VELO.

IV. RESULTS

In Fig. 6 I show the \( q_{\text{reco}}^2 \equiv (p_B - p_K)^2 \) normalized distribution over the full range \( q_{\text{reco}}^2 \in [m_\epsilon^2, (m_B - m_K)^2] \),
generated by \( B \to K(\pi^0 \to ee\gamma)\gamma \) from the above simulation. Multiplying by the normalization factor
\[
N \equiv \int dx \frac{|F(s)|^2}{\pi} \frac{\text{Br}[\pi^0 \to ee\gamma]}{\text{Br}[\pi^0 \to \gamma\gamma]} \simeq (3.0 \pm 0.2) \times 10^{-7}, \tag{9}
\]
yields the differential branching ratio, including only the leading uncertainties from the \( V = K^* \) contribution. I have dropped the remaining uncertainties from the data in Table I that enter into \( F(s) \), since we are interested only in an estimate, and such uncertainties will be subleading compared to the MC uncertainties from the simulation.

Also shown in Fig. 6 in blue is the differential distribution keeping only those events that satisfy the Bremsstrahlung recovery algorithm in Sec. III B. The fraction of events for which both photons in \( B \to K(\pi^0 \to ee\gamma)\gamma \) are misreconstructed as Bremsstrahlung in the \( 1 < q_{\text{reco}}^2 < 6 \text{GeV}^2 \) signal regime is estimated as
\[
\frac{f_{\text{misreco}}}{\text{Br}[B^+ \to K^+\mu\mu]} = \begin{cases} 
(0.31 \pm 0.08)\% & [Bd\ell = 0.1 \text{ Tm}], \\
(1.2 \pm 0.3)\% & [Bd\ell = 0.3 \text{ Tm}] 
\end{cases}, \tag{10}
\]
where the uncertainty is purely from MC, and I show results for the conservative and plausible values for the bending power, as discussed in Sec. III B. Multiplying by the normalization factor \( N \) yields the corresponding branching ratio for the misreconstruction.

The effect of the \( p_T \) threshold is significant: Without this cut, \( f_{\text{misreco}} \) would significantly increase to \((1.7 \pm 0.4)\% \) and \((4.8 \pm 0.7)\% \), for the conservative and plausible bending power values, respectively. This suggests tighter \( p_T \) thresholds may entirely suppress the contribution from misreconstructed \( B \to K(\pi^0 \to ee\gamma)\gamma \) decays altogether. Setting a lower bound \( \theta_{\text{det}} > 5 \times 10^{-3} \) does not enhance the misreconstruction fraction beyond the MC uncertainties in Eq. (10), so that the ECAL resolution effects appear to be subleading. Similarly, including the case that the \( \pi^0 \) daughter photon is soft, below a conservative 75 MeV threshold for Bremsstrahlung recovery [19], leads to a negligible increase in \( f_{\text{misreco}} \).

The measured branching ratio \( \text{Br}[B^{+} \to K^{+}\mu\mu] = 1.2(1) \times 10^{-7} \) [25]. Taking this as a proxy for the true \( B^+ \to K^+ee \) branching fraction assuming no LFUV, then the fractional enhancement in the measured \( B^+ \to K^+ee \) branching fraction with misreconstruction is
\[
\frac{N f_{\text{misreco}}}{\text{Br}[B^+ \to K^+\mu\mu]} \simeq \begin{cases} 
(0.8 \pm 0.2)\% & [Bd\ell = 0.1 \text{ Tm}], \\
(3.1 \pm 0.8)\% & [Bd\ell = 0.3 \text{ Tm}] 
\end{cases}. \tag{11}
\]

Thus, one roughly expects in the SM the recovered ratio could decrease to \( R_{K}^{\text{rec}} \simeq 0.99 \pm 0.005 \) and \( 0.97 \pm 0.01 \), respectively. The latter shift is comparable to the size of the combined statistical and systematic uncertainties quoted in Ref. [4].

V. SUMMARY AND OUTLOOK

The \( \pi^0 \to ee\gamma \) Dalitz decays of neutral pions produced in \( b \to s\gamma \) processes may generate an additional sources of uncertainty in precision measurements of the LFUV ratios, \( R_{K^{(*)}} \), if the photons are misreconstructed into the \( \pi^0 \) daughter leptons as Bremsstrahlung. In this note, an approximate Breit-Wigner parametrization for the resonant contributions \( B \to (V \to K\pi^0)\gamma \) was combined with a conservative guess estimate of the implementation for Bremsstrahlung recovery at LHCb, to produce an approximate simulation of the contributions to \( R_{K} \) from misreconstruction of \( B \to K(\pi^0 \to ee\gamma)\gamma \). This simulation suggests a LFUV background present at the percent level in \( R_{K} \) from \( B \to K\pi^0\gamma \) alone, that could be as large as 3%, depending on the magnetic bending power. For two cases of \( f_{Bd\ell} = 0.1 \text{ Tm} \) and 0.3 Tm, the recovered ratio in the SM would be expected to decrease to \( R_{K}^{\text{rec}} \simeq 0.99 \pm 0.005 \) and \( 0.97 \pm 0.01 \), respectively. The same effect, at the same order of magnitude, may occur in \( R_{K^{(*)}} \) measurements. Other \( b \to s\gamma \) transitions involving (pseudo)scalars such as \( B \to K\eta'\gamma \), \( \eta' = \eta,\eta', \ldots \) may further enhance \( R_{K} \), because of their enhanced Dalitz decay to \( ee\gamma \) near the photon pole. Whether modes such as \( B \to K\pi^0\pi^0\gamma \) may also contribute similarly to \( R_{K} \) requires further study.

Keeping in mind that: (i) I have likely underestimated the \( B \to K\pi^0\gamma \) branching ratio; (ii) the effective bending power of the LHCb magnet could be even greater than the 0.3 Tm estimate; and; (iii) there may be other reconstruction resolution effects, that loosen the effective allowable angular displacement of a photon versus a lepton in order for the former to be recovered as upstream Bremsstrahlung, it is not inconceivable that the effect on \( R_{K^{(*)}} \) could \( \mathcal{O}(1) \) greater than estimated here. Of course, it is also conceivable that: (iv) the Bremsstrahlung recovery at LHCb could be far better able to discriminate or reject fakes than estimated above, and; (v) the reconstruction efficiency for the \( B \to K(\pi^0 \to ee\gamma)\gamma \) background could be much lower than for the signal, leading to a substantial suppression of the effect on \( R_{K^{(*)}} \). A proper estimate of this effect will require dedicated studies within experimental frameworks, not only at LHCb but also at Belle II.

If the effect is present, then precision measurements of the LFUV ratios \( R_{K^{(*)}} \) will require improved theoretical descriptions of \( B \to K\pi^0\gamma \)-like backgrounds, which feature notable hadronic uncertainties. If such a scenario arises, this will be (yet another) example of a theoretically clean observable that acquires nontrivial theoretical uncertainties when recovered from a precision experimental framework.

ACKNOWLEDGMENTS

I thank Florian Bernlochner, Marat Freytsis, Zoltan Ligeti, Michele Papucci and Maayan Robinson for discus-
sitions and for their comments on the manuscript. I further thank Marat Freytsis for pointing out the possibility of contributions from other modes such as $B \rightarrow K\pi^0\pi^0\gamma$, and I thank the Referees for their comments and observations, in particular pointing out the importance of $p_T$ selections for the leptons.
