(Dated: 2022 May 26)

Beginning with precise data on the ratio of structure functions in deep inelastic scattering (DIS) from $^3$He and $^3$H, collected on the domain $0.19 \leq x_B \leq 0.83$, where $x_B$ is the Bjorken scaling variable, we employ a robust method for extrapolating such data to arrive at a model-independent result for the $x_B = 1$ value of the ratio of neutron and proton structure functions. Combining this with information obtained in analyses of DIS from nuclei, corrected for target-structure dependence, we arrive at a prediction for the proton valence-quark ratio: $d_v/u_v|_{x_B=1} = 0.230(57)$. Requiring consistency with this result presents a challenge to many descriptions of proton structure.

1. Introduction — In the Standard Model of particle physics, there are two flavours of light quark – up ($u$) and down ($d$) – quarks; and the proton is comprised of two valence $u$ quarks and one valence $d$ quark, which are bound by the exchange of gluons, viz. the gauge bosons of quantum chromodynamics (QCD). Such valence-quarks are not the constituent quarks [1, 2] used to build quantum mechanics descriptions of the properties of baryons (neutrons, protons, etc.) [3–5], although links can be drawn between them [6, Sec. 2.3]. Moreover, quantum field theory is far more complex than quantum mechanics, whilst preserving all its basic features. These things together mean that any attempt to express the proton wave function in terms of QCD’s Lagrangian degrees-of-freedom will require infinitely many terms [7], each one containing different numbers of gluons, quarks and antiquarks. Approached this way, the problem of solving for the proton wave function has thus far been intractable.

Notwithstanding the challenges involved, the proton wave function is a very desirable quantity. Indeed, analogous to the wave function for the hydrogen atom, a sound result for the proton wave function, $\Psi_p$, would enable many basic features of QCD to be understood. For instance, even though it is impossible to speak of their precise number, with $\Psi_p$ in hand one can compute matrix elements that express the number density distributions within the proton of QCD’s gluons and quarks, i.e., the proton parton distribution functions (DPs) [8, Sec. 4].

The proton DFs have long been the subject of intense study [9–12]. They can be inferred from measurements using, e.g., the deep inelastic scattering (DIS) process drawn in Fig. 1, when the kinematic variables satisfy the Bjorken conditions [13]. It was using just such processes that quarks were discovered [14–17].

Returning to the issue of valence quarks, given that the proton is that object which appears as the lowest-mass bound-state in the scattering of two $u$-quarks and one $d$ quark, it is natural to ask for the ratio of $u$ and $d$ quark number densities in this system. Importantly, the value of this ratio on the far-valence domain, $x_B \approx 1$, is one of the keenest available discriminators between competing descriptions of proton structure [18]; and neutron ($n$) structure, too, because SU(2)-flavour (isospin) symmetry is an accurate approximation for strong interactions.

Before considering possible answers, it is first necessary to observe that the simplest description of high-energy scattering processes is obtained by formulating the problem using light-front coordinates, in which case
one writes the proton’s four-momentum $P = (P_0, \vec{P}) = (P_t, P_z, P_\perp, P_\parallel)$ with $P_0 = |\vec{P}_\perp|^2 + m_0^2 / P_\perp$. Formulated in these terms, then at leading order in analyses using perturbative QCD, the Bjorken variable, $x_B$ in Fig. 1, can be identified with the light-front fraction of the proton’s momentum carried by the parton which participates in the scattering process [20, 21]: $x = l_+ / P_\perp$. The proton DFs are then accessible, e.g., via projection of the proton’s Poincaré covariant wave function onto the light-front.

Maintaining Poincaré covariance in calculations of the proton wave function and DIS observables is crucial. Yet, results based on nonrelativistic quark model wave functions are still cited. The simplest of these are based on few-body quantum mechanics, with two-body potentials {19]. Formulated in these terms, then at leading order in terms of QCD’s Lagrangian degrees-of-freedom.

It is now known [25] that $d_s(x) / u_s(x) \neq 1$, deviating by possibly as much as a factor of 1.5 on $0.1 < x < 0.4$. Nevertheless, in comparison with valence DFs, all sea distributions in Eq. (1) are negligible on $x \gtrsim 0.2$ (see, e.g., Ref. [26, Ch. 18] and the discussions in Refs. [27, 28]); hence:

$$\frac{F_2^p(x)}{F_2^n(x)} \leq 4 d_s(x) / u_s(x)$$

The limiting cases $d_s(x) \equiv 0$ and $u_s(x) \equiv 0$ yield the Nachtmann bounds [29]:

$$1/4 \leq F_2^p(x) / F_2^n(x) \leq 4$$

Owing to scaling violations [8, Sec. 4], $F_2^p(x) / F_2^n(x)$ actually depends on the $Q^2$ value at which it is measured; except at the endpoint $x = 1$, where the ratio is a fixed point under QCD evolution [9]. This feature, which can be verified by adapting the analysis in Ref. [30, App. A], is what empowers the ratio $d_v(x) / u_v(x)$ as an acute discriminator between pictures of proton structure.

3. Structure function ratio: experiment — The proton is stable and has been used as a target in high-energy experiments for almost one hundred years [31]. Isolated neutrons, however, decay rather quickly; so the big issue in obtaining reliable measurements of $F_2^p(x) / F_2^n(x)$ is centred on the construction of a “free neutron” target. Beginning with Refs. [22, 23], many experiments have used the deuteron as the path to a neutron target; but even though this is a weakly bound system, the characterisation of proton-neutron interactions introduces a large theory uncertainty in the extracted ratio on $x \gtrsim 0.7$ [32].

A different approach is to perform DIS measurements on $^3$He and $^3$H and then take the ratio of scattering rates from these two nuclei. In this case, nuclear interaction effects largely cancel when extracting $F_2^p(x) / F_2^n(x)$ [33, 34]. The challenge here is developing a method for handling the radioactive $^3$H target; but after years of development, such an experiment was recently completed [24]. Adding credibility to these new results, the data obtained is, within mutual uncertainties, in agreement with an analysis of nuclear DIS reactions, on targets ranging from the deuteron to lead, which accounts for the impact of short-range correlations in the nuclei [35].

The possibility that MARATHON data omit a systematic effect deriving from model-dependent assumptions about nuclear structure is raised in Refs. [36, 37]. More analyses are required before this hypothesis can be validated and its potential impact reliably quantified. We therefore proceed with analysis of the data reported in Ref. [24].

The MARATHON data, reproduced in Fig. 2, have good coverage of the domain $x \in [0.195, 0.825]$ and reach closer to $x = 1$ than previous measurements. Hence, they are well suited for analysis using a newly developed technique to extract an $x = 1$ value for $F_2^p(x) / F_2^n(x)$ with a well-defined uncertainty. The approach, typically described as the statistical Schlessinger point method (SPM) [38, 39], has been refined in many hadron physics applications, especially those which demand model-independent interpolation and extrapolation [40–50]. The SPM avoids any specific choice of fitting function, generating form-unbiased interpolations of data as the basis for well-constrained extrapolations. Hence, the $x = 1$ value produced is model independent, expressing only the information contained in the data.

4. Form-unbiased, data-informed extrapolation — The SPM builds a large set of continued fraction interpolations, with each element of the set capturing both local and global features of the curve underlying the data. The global aspect is vital, guaranteeing the validity of the in-
generated by replacing each datum by a new point, distributed randomly around a mean defined by the datum itself with variance equal to its associated error. The fact that \( M \) is not fixed introduces a second source of error, \( \sigma_M \), whose magnitude we estimate by shifting \( M \rightarrow M' \), repeating the aforementioned procedure using \( M' \), and evaluating the standard deviation of the distribution of \( F_2^2(x)/F_2^P(x) \) for all different \( M \) values.

Consequently, the SPM result for \( R(x) := F_2^2(x)/F_2^P(x) \) is \( R(x) \pm \sigma_R(x) \), where:

\[
R(x) = \sum_{M=6}^{15} \frac{R_M(x)}{10}; \quad \sigma_R(x) = \sqrt{\frac{\sum_{M=6}^{15} (\frac{\sigma_M}{\sigma_R(x)})^2}{10^5} + \sigma_M^2}. \tag{4b}
\]

At each point \( x \in [0, 1] \), we have 10-million results for the ratio, \( R(x) \), each calculated from an independent interpolating function.

As checks on internal consistency, we also implement this same procedure for the ratio \( d_v(x)/u_v(x) \), constructed from the MARATHON data using Eq. (2), and the primary structure function ratio measured by the Collaboration, viz. \( \sigma_v/\sigma_h = F_2^2/F_2^P, h = ^{3}\text{He}, t = ^{5}\text{H} \).

5. Validation of SPM extrapolation — Before reporting results, it is first worth demonstrating that the SPM delivers reliable extrapolations when used in connection with the MARATHON data set. This is achieved following the procedure explained in Ref. [48, Supp. Mat.].

We first select a known functional form for the ratio \( d_v(x)/u_v(x) \). Any smooth function consistent with Eq. (3) will suffice. We choose the CJ15 result, determined in Ref. [53] through a next-to-leading-order global fit to a range of then available data, because that study made a deliberate attempt to reduce uncertainty in \( d_v(x)/u_v(x) \) at large-\( x \), returning the result

\[
\lim_{x \rightarrow 1} d_v^{CJ15}(x)/u_v^{CJ15}(x) = 0.09(3). \tag{5}
\]

Working with the known central function, \( R_{15}(x) := d_v^{CJ15}(x)/u_v^{CJ15}(x), \) we generated replica data sets built from values of this ratio at the \( x \)-points sampled in the MARATHON experiment. The character of real data is modelled by introducing fluctuations drawn according to a normal distribution.

Treating this new set of data as real, we applied the SPM procedure described above. Namely: (i) generate \( 10^3 \) replicas; (ii) smooth each replica with the associated optimal parameter; (iii) use the SPM to obtain \( R_{15}(1) \) and \( \sigma_{R_{15}(1)} \), varying the number of input points \( \{M_j = 5 + j \mid j = 1, \ldots, 10\} \); and (iv) calculate the final SPM result. In this way, we obtained \( F_2^{SPM}(1) = 0.10(5) \), i.e., reproducing the input value with a 93% level of confidence. If one regards the amount of curvature on \( x \geq 0.7 \) in the CJ15 fits [53, Fig. 14], this will be recognised as a keen test and clear validation of the SPM.
We remark that in connection with the extrapolation to \( x = 1 \), there is a discernible sensitivity to the value of \( M \), so that \( \sigma_{3M} \) dominates in Eq. (4b). This was not the case when using the SPM to extract the proton charge radius [48]; and owes herein to the relative paucity and lower precision of the MARATHON data when compared with that reported for the proton form factor in Ref. [54]. This is a mathematical statement, with no other interpretations intended: the \( \sigma_l/\sigma_h \) measurement is challenging. Similar observations have been made in connection with the pion charge radius [49].

6. SPM results from MARATHON — Our SPM results for \( \sigma_l/\sigma_h, F_n^p/F_p^p, d_e/u_v \) are drawn in Fig. 2. Each set of points was analysed independently so that consistency between the various results can serve as additional validations of the method.

Consider first the behaviour on \( x \approx 0 \). Our independent SPM analysis of each data set drawn in Fig. 2 yields:

\[
\begin{align*}
\sigma_l/\sigma_h & \quad F_n^p/F_p^p & \quad d_e/u_v \\
\mathcal{F}_X(F) & = 0.962 \pm 0.245, & = 1.026 \pm 0.139, & = 1.323 \pm 0.706.
\end{align*}
\]

Although the statistical uncertainties are significant, especially for \( d_e/u_v \), all results are consistent with sea-quark dominance on \( x \approx 0 \); an outcome expected in any experiment consistent with DIS kinematics.

Turning now to the neighbourhood \( x \approx 1 \), the SPM returns the following limiting values:

\[
\begin{align*}
\sigma_l/\sigma_h & \quad F_n^p/F_p^p & \quad d_e/u_v \\
\mathcal{F}_X(F) & = 0.437 \pm 0.085, & = 0.754 \pm 0.052, & = 0.227 \pm 0.100.
\end{align*}
\]

Remark 1. \( \sigma_l/\sigma_h \) data are the source for the \( F_n^p/F_p^p \) results. At each \( x \), the relation between them is determined by a single number, \( R_{1/2} \), an EMC ratio [12, 55, 56], that should be close to unity, e.g., [24, Eq. (2)]. Using the results in Eq. (7), one finds \( R_{1/2}(x=1) \approx 1.019(13) \).

Remark 2. The \( d_e/u_v \) points in Fig. 2 were obtained from those for \( F_n^p/F_p^p \) using Eq. (2). The results in Eq. (7) were obtained via independent SPM treatments of the two data sets. Using that for \( F_n^p/F_p^p \) in Eq. (2), one finds \( d_e/u_v = 0.212(10), i.e., a value just 0.14 \sigma \) away from that determined using the SPM on the \( d_e/u_v \) points.

7. Conclusions — Fig. 3 compares our MARATHON-based SPM prediction for \( F_n^p/F_p^p \) with: the value inferred from nuclear DIS [35]; theory predictions [57–60]; and the result from the phenomenological fit in Ref. [53].

The Nachtman lower bound, Eq. (3), is also highlighted in Fig. 3. It is saturated if valence d-quarks play no material role at \( x = 1 \), i.e., when there are practically no valence d-quarks in the proton: \( d_e/u_v \approx 0 \). The result is characteristic of models for the proton wave function in which the valence d-quark is always sequestered with one of the valence u-quarks inside a \( J^P = 0^+ \) “diquark” correlation [61–63]. Even allowing for the quark-exchange dynamics typical of Poincaré-covariant Faddeev equation treatments of the proton [63], one still finds \( d_e/u_v \approx 0 \) if only scalar diquarks are retained [58].

Observation 1. Considered alone, the SPM prediction, Eq. (7), excludes the result \( F_n^p/F_p^p \approx 1 \) with a 99.7% level of confidence; hence, models of the proton wave function that only include scalar diquarks are excluded with equal likelihood. Conversely, the QCD parton model prediction [59, 60]: \( d_e(x) \propto u_v(x) \approx 1 \), is confirmed with this same level of confidence.

Observation 2. The SPM prediction is consistent with the result inferred from nuclear DIS [35]. The average of these results is drawn at row 3 in Fig. 3:

\[
F_n^p/F_p^p \mid_{SPM \& DIS-A} = 0.454 \pm 0.047.
\]

In this case, the probability that scalar diquark models might be consistent with available data is 0.000014%. If Eq. (3) is removed as a constraint on SPM interpolants, only the uncertainty in Eq. (8) changes: 0.047 \( \rightarrow \) 0.054.

Observation 3. Eq. (8) is consistent with both: \( a \) the result obtained by assuming an uncorrelated SU(4) spin-flavour proton wave function and helicity conservation in high-\( Q^2 \) interactions [59, 60]; and \( b \) the prediction from a Poincaré-covariant Faddeev equation approach to proton structure in which, owing to the mechanisms underling the emergence of hadron mass [6, 64], both \( J^P = 0^+ \) and \( J^P = 1^+ \) diquark correlations are generated with a dynamically determined relative strength [57, 58].

It is here worth noting a strong theory constraint. Namely, the proton’s Poincaré covariant bound-state amplitude involves 128 independent Dirac structures, only a small number of which correspond to configurations with...
a quark+scalar-diquark character [65–67]. Consequently, Poincaré covariance alone is sufficient to guarantee the presence of additional diquark-like structures in any realistic proton wave function.

In summary, profiting from a combination of today’s empirical understanding of target-dependent effects in deep inelastic scattering (DIS), new precise data on the ratio of structure functions in DIS from \(^3\)He and \(^3\)H, and a robust method for analysing and extrapolating such data, we arrive at the following result for the proton valence-quark ratio:

\[
\lim_{x \to 1} \frac{d_u(x)}{u_u(x)} = 0.230 \pm 0.057. \tag{9}
\]

With a high level of confidence, proton structure models that are inconsistent with Eq. (9) can be discarded.
