Abstract

We re-examine the charm contribution to atmospheric lepton fluxes in the context of perturbative QCD. We include next-to-leading order corrections and discuss theoretical uncertainties due to the extrapolations of the gluon distributions at small-\(x\). We show that the charm contribution to the atmospheric muon flux becomes dominant over the conventional contribution from \(\pi\) and \(K\) decays at the energies of about \(10^5\) GeV. We compare our fluxes with previous calculations.

I. INTRODUCTION

Neutrino and muon fluxes from cosmic ray interactions with the Earth’s atmosphere have been topics of considerable experimental and theoretical interest \([1]\). At energies near 1 GeV, the IMB \([2]\), Kamiokande \([3]\) and Soudan \([4]\) experiments detect an excess of \(\nu_e\) relative to \(\nu_\mu\) in the atmospheric neutrinos. Recent results from SuperKamiokande \([5]\) appear to confirm this observation. At these energies, leptonic decays of charged pions and leptonic and semileptonic decays of kaons are responsible for the lepton fluxes, the so-called “conventional” lepton flux. Currently, it is believed that the conventional flux dominates until energies of about \(10^3\) TeV, when the effects of atmospheric charm production and decay become important contributions to the lepton fluxes. The issue of where the charm contributions dominate is of interest, in part, because this is an energy regime accessible to large underground experiments \([6]\). Recent results from Fréjus \([7]\), Baksan \([8]\) and other experiments \([9]\) show an excess relative to the conventional muon flux in the 10 TeV energy range. This may be an indication of a charm contribution at lower energies that expected. One of the main goals of the neutrino experiments such as AMANDA \([10]\), Antares \([11]\), Nestor \([12]\) and at Lake Baikal \([13]\) are searches for muon neutrinos from extragalactic neutrino sources for which atmospheric neutrinos and muons present the main background.

Lepton fluxes from atmospheric charm have been calculated previously \([14–17]\) for specific models of charm particle production. Here, we calculate the leptonic flux from charm in the context of perturbative QCD. We include next-to-leading order radiative corrections and we study the importance of small-\(x\) behavior of the parton distribution functions. We emphasize the uncertainties inherent in the necessary extrapolation of cross sections and energy distributions beyond the experimentally measured regime. We use the comparison with low-energy charm production data to constraint some of the theoretical uncertainties,
such as the charm quark mass and the factorization and renormalization scale dependence. We compare our results to the earlier work on the prompt muons from charm including a recent calculation [14] calculated using PYTHIA Monte Carlo program [18].

In the next section, we describe the framework for the calculation of the lepton fluxes. In Section III, we focus on the charmed quark contribution. In Section IV, we present our results for the fluxes and compare with other calculations. We conclude in Section V.

II. LEPTON FLUX CALCULATION

Particle fluxes are determined by solving the coupled differential equations that account for production, decays and interactions of the particles. The general form of the cascade equations describing the propagation of particle $j$ through column depth $X$ is given by

$$\frac{d\phi_j}{dX} = -\frac{\phi_j}{\lambda_j} - \frac{\phi_j}{\lambda_{j}^{(dec)}} + \sum_k S(k \rightarrow j)$$

(2.1)

where $\lambda_j$ is the interaction length, $\lambda_j^{(dec)} \simeq \gamma c T_j \rho(X)$ is the decay length, accounting for time dilation factor $\gamma$ and expressed in terms of g/cm$^2$ units. The density of the atmosphere is $\rho(X)$ and

$$S(k \rightarrow j) = \int_{E}^{\infty} dE_k \frac{\phi_k(E_k, X) \text{dn}_{k \rightarrow j}(E; E_k)}{\lambda_k(E_k)} .$$

(2.2)

In Eq. (2.2), $\text{dn}/dE$ refers to either the production distribution $1/\sigma_k \cdot d\sigma_{k \rightarrow j}/dE$ or decay distribution $1/\Gamma_k \cdot d\Gamma_{k \rightarrow j}/dE$ (where $\lambda_k \rightarrow \lambda_k^{(dec)}$ in Eq. (2.2)) as a function of the energy $E$ of the outgoing particle $j$.

It is possible to solve these equations numerically, however, it has been shown [14] that the same results can be obtained with an analytic solution which was derived by noticing that the energy dependence of the fluxes approximately factorizes from the $X$ dependence. Consequently, one can rewrite

$$S(k \rightarrow j) \simeq \frac{\phi_k(E, X)}{\lambda_k(E)} \int_{E}^{\infty} dE_k \frac{\phi_k(E_k, 0) \lambda_k(E_k)}{\phi_k(E, 0) \lambda_k(E_k)} \text{dn}_{k \rightarrow j}(E; E_k)$$

(2.3)

$$\equiv \frac{\phi_k(E, X)}{\lambda_k(E)} Z_{kj}(E) .$$

It is often convenient to write $Z_{kj}$ in terms of an integral over $x_X \equiv E/E_k$, so

$$Z_{kj}(E) = \int_{0}^{1} \frac{dx_X \phi_k(E/x_X, 0)}{\phi_k(E, 0)} \frac{\lambda_k(E)}{\lambda_k(E/x_X)} \text{dn}_{k \rightarrow j}(E/x_X) .$$

(2.4)

In the limits where the flux has a single power law energy behavior, the interaction lengths are energy independent and the differential distribution is scaling (energy independent), the Z-moment $Z_{kj}(E)$ is independent of energy. In practice, the $Z$-moments have a weak energy dependence because $\text{dn}/dx_X$ depends on $E_k$, the interaction lengths $\lambda$ are not energy
independent, and in general, $\phi_k(E)$ is not a constant power law in energy over the full energy range. The cosmic ray flux can be represented by the following flux of primary nucleons at $X = 0$:

$$\phi_p(E, X = 0) \text{[cm}^{-2}\text{s}^{-1}\text{sr}^{-1}\text{GeV}^{-1}] = \begin{cases} 1.7 \frac{(E/\text{GeV})^{-2.7}}{174 \frac{(E/\text{GeV})^{-3}}{E < E_0} \quad E \geq E_0 , \end{cases}$$

where $E_0 = 5 \cdot 10^6 \text{ GeV}$ \cite{1,22}. At these energies, we assume isotropy of the flux \cite{23}.

The detailed solutions to the cascade equations can be found, for example, in Refs. \cite{19} and \cite{20}. Following Ref. \cite{14}, we assume that the incident cosmic ray flux can be represented by protons. The flux results, in high energy and low energy regimes for lepton flavor $\ell = \nu_\mu$, $\nu_e$ or $\mu$ due to proton production of hadron $j$ followed by $j$ decay into $\ell$ are

$$\phi_{j,\text{high}}^{\ell} = \frac{Z_{pj}(E)Z_{jl}(E) \ln(\Lambda_j/\Lambda_p) m_j c h_0}{1 - Z_{pp}(E)} \frac{m_j c h_0}{E \tau_j} f(\theta) \phi_p(E, 0),$$

$$\phi_{j,\text{low}}^{\ell} = \frac{Z_{pj}(E)Z_{jl}(E)}{1 - Z_{pp}(E)} \phi_p(E, 0),$$

where an isothermal model for the atmosphere, in which $\rho(h) = \rho_0 \exp(-h/h_0)$ describes the density profile as a function of altitude $h$. The parameters are $h_0 = 6.4 \text{ km}$ and $\rho_0 = 2.03 \times 10^{-3} \text{ g/cm}^3$ \cite{24}. The quantity $m_j$ is the decaying particle’s mass and

$$\Lambda_j \equiv \frac{\lambda_j}{(1 - Z_{jj})}$$

is an effective interaction length, which is weakly dependent on energy. The zenith angle dependence of the high energy flux is characterized by $f(\theta) \sim 1/\cos \theta$ for $\theta < 60^\circ$. At higher zenith angles, $f(\theta)$ is a more complicated function which accounts for the curvature of the earth. Details appear in Ref. \cite{20}. The low energy flux is isotropic. When the cascade involves charm hadrons, the low energy behavior dominates and the flux is called “prompt”. Critical energies, below which the decay length is less than the vertical depth of the atmosphere, range from $3.7 - 9.5 \times 10^7 \text{ GeV}$ \cite{14}. Interpolation between high and low energy fluxes is done via

$$\phi_\ell = \sum_j \frac{\phi_{j,\text{low}}^{\ell} \phi_{j,\text{high}}^{\ell}}{\phi_{j,\text{low}}^{\ell} + \phi_{j,\text{high}}^{\ell}}.$$

Eqs. (2.6) and (2.7) show that the bases for the calculation of the prompt lepton fluxes are production and decay $Z$-moments involving charm. The decay moments are discussed in Section III.D. The main uncertainties in the calculation of the lepton flux from atmospheric charm are the production $Z$-moments: $Z_{pD}$ and $Z_{p\Lambda_c}$. The production moments are given by

$$Z_{pc} = 2 \int_0^1 \frac{d\sigma_{\text{p}A} \phi_p(E/x_E)}{d\sigma_{\text{p}A}(E)} \frac{1}{x_E} \frac{d\sigma_{\text{p}A \rightarrow c \bar{c}}(E/x_E)}{d\sigma_{\text{p}A}(E)}.$$

(2.10)
The differential cross section is evaluated here using perturbative QCD. The factor of two accounts for the multiplicity of charmed (or anticharmed) particles. The charm \( Z \)-moments can be converted to hadronic moments by

\[
Z_{pj}(E) = f_j Z_{pc}(E),
\]

where \( f_j \) is the fraction of charmed particles which emerges as hadron \( j \), where \( j = D^0, D^+, D_s^+ \) and \( \Lambda_c \). We implicitly sum over particles and antiparticles (hence the factor of two in Eq. (2.10)).

The inelastic proton-air cross section \( \sigma_{pA}(E) \) is parameterized by

\[
\sigma_{pA}(E) = 280 - 8.7 \ln(E/\text{GeV}) + 1.14 \ln^2(E/\text{GeV}) \text{ mb}.
\]

In the high energy limit of the lepton fluxes, in addition to \( Z_{pc} \), we need effective hadronic interaction lengths \( \Lambda_j \). The proton effective interaction length is therefore

\[
\Lambda_p(E) \simeq \frac{A}{N_0 \sigma_{pA}(E)} \frac{1}{1 - Z_{pp}}
\]

where \( A = 14.5 \) is the average atomic number of air nuclei and \( N_0 = 6.022 \times 10^{23}/\text{g} \). We use Thunman et al.’s (TIG) energy dependent \( Z_{pp} \), calculated using a PYTHIA Monte Carlo [18] as a function of energy [14]. The charmed hadron \( j \) interaction lengths are all taken to be equal to the kaon interaction length, approximated by

\[
\Lambda_j \simeq \frac{A}{N_0 \sigma_{pA}(E) \sigma_{tot}^{pp}(E)} \frac{1}{1 - Z_{KK}}.
\]

We use \( Z_{KK} \) from Ref. [14]. The total cross sections are parameterized using the particle data book values [24] based on Regge theory [27]. The prompt lepton flux below \( 10^8 \) GeV is insensitive to the detailed values of \( \Lambda_j \) because essentially all of the charmed hadrons decay before reaching the surface of the earth. Therefore, for most of the energy range considered here, the charmed particles are “low energy” and Eq. (2.7) describes the lepton fluxes.

We now turn to the evaluation of \( Z_{pc} \) in perturbative QCD and the other charm inputs.

### III. CHARM CROSS SECTION AND ENERGY DISTRIBUTION

The charm production cross section and energy distribution are the largest uncertainties in the calculation of the prompt lepton fluxes. Since the charm quark mass is of the order of 1.3 GeV, the treatment of the charm quark as a heavy quark may be questionable. Theoretical uncertainties, due to the possible range of charm quark masses, as well as the usual factorization and renormalization scale dependence need to be studied. Theoretical predictions based on perturbative QCD calculation fit the available data reasonably well in the energy range up to 800 GeV beam energy [28]. However, atmospheric lepton flux calculations require beam energies up to and beyond \( 10^8 \) GeV. The parton distribution functions are needed at very small parton momentum fraction \( x \), outside of the measured regime [27].

In this section we will address these theoretical issues:
• the effect of next-to-leading order corrections on the cross section and charmed particle energy distribution,
• charmed quark mass dependence,
• factorization and renormalization scale dependence,
• the consequences of the small-\(x\) behavior of the parton distribution functions on the interaction \(Z_{p_c}\) moment, and
• the \(A\) dependence of the proton-air charm production cross section.

From our evaluation of these quantities, a theoretical uncertainty associated with perturbative charm production will be evaluated. We also describe our inputs to the decay moments of charmed hadrons.

A. Total Cross Section

The next-to-leading order (NLO) total charm cross section has been calculated by Nason, Dawson and Ellis \[30\] and by van Neerven and collaborators \[31\]. The NLO cross section is a factor of between 2 and 2.5 larger than the leading order cross section. Gluon fusion dominates the production process. In Fig. 1, we show the importance of the charm quark mass in the NLO cross section. We compare the NLO \(\sigma(pN \rightarrow c\bar{c}X)\) as a function of the beam energy \(E\) obtained with the renormalization scale \(\mu\) equal to the factorization scale \(M\) equal to the charm quark mass \(m_c\) with \(m_c = 1.3\) GeV and \(m_c = 1.5\) GeV. The cross sections are evaluated using the CTEQ3 parton distribution functions \[32\]. The corresponding value of \(\Lambda_{\overline{MS}}^4\) is 239 MeV. Fixed target data from a summary by Frixione et al. \[33\] are also plotted. We note that the fixed target data seem to prefer \(m_c = 1.3\) GeV. In all of the subsequent figures, we set \(m_c = 1.3\) GeV. The CTEQ3 parton distribution functions will be our canonical set, in part because they incorporate global fits to HERA data, and while their validity is not claimed for parton fraction \(x\) below \(x_{\text{min}} = 10^{-5}\) and \(Q_0 = 1.6\) GeV, the program nevertheless provides smooth parton distribution functions below these values.

In Fig. 2 we show dependence of the total cross section on the scale and parton distribution. We plot the NLO cross section for different values of \(\mu\) and \(M\): using the CTEQ3 structure functions, we set \(\mu = M = m_c\) (dot-dashed) and \(\mu = m_c, M = 2m_c\) (solid) with \(m_c = 1.3\) GeV. The dashed line is the cross section obtained with the MRSD- parton distribution functions \[34\] and scales \(\mu = m_c, M = 2m_c\) with \(m_c = 1.3\) GeV. Also plotted are the data as in Fig. 1.

The MRSD- distribution functions have a small-\(x\) behavior that is suggested by the BFKL approach \[35\]. In the small-\(x\) limit, the parameterization of the gluon (and sea quark) distribution functions at reference scale \(Q_0\) is

\[
xg(x, Q_0) \sim x^{-\lambda}.
\]

The D- distributions have \(\lambda = 0.5\). Typically, global fits such as the MRSA \[36\], MRSG \[37\] and CTEQ3 distributions have \(\lambda \simeq 0.3\). By using the D- distributions, we are effectively setting an upper limit on the perturbative charm cross section, given our choices of \(m_c, \mu\)
and $M$. We note that, generally, parton distribution functions begin evolution at $Q_0$ larger than 1.3 GeV. Consequently, our default factorization scale is $M = 2m_c$ so that we can use more than the CTEQ3 parameterizations.

Fig. 2 indicates that at low energies, the total cross section has weak dependence on the choice of the scale and the parton distribution function. At high energies, $E \geq 10^6$ GeV, there is a factor of 1.7-2.1 increase from $M = m_c$ to $M = 2m_c$. The D- cross section is a factor of 1.3 larger than the CTEQ3 cross section at $E = 10^6$ GeV, both with $M = 2m_c$. The D- cross section increases more rapidly because of the steeper small-$x$ behavior of the parton distribution function and is enhanced by a factor of 2.6 at $10^8$ GeV. This gives an overall uncertainty of factor of 5.5 at the highest energy of $10^8$ GeV. The MRSA and MRSG cross sections for $M = 2m_c$ lie between the upper and lower curves in Fig. 2.

The total charm cross section in p-Air collisions, $\sigma_{pA \to c \bar{c}}(E)$, can be written as

$$\sigma_{pA \to c \bar{c}} = A^\gamma \sigma_{pN \to c \bar{c}}$$

We have evaluated the $A$ dependence for charm pair production using a Glauber-Gribov model of nuclear shadowing [38]. We find that over an energy range of $10^2 - 10^6$ GeV, $\gamma = 1.0 - 0.8$. Since $A = 14.5$, the shadowing effect is small, so we set $\gamma = 1$. This is consistent with recent measurements at $E = 800$ GeV [39]. Low energy measurements at larger $x_E$ [10] indicate smaller $\gamma$ values ($\gamma \approx 0.75$), which would reduce our flux predictions by an overall factor of 0.5.

We have used a comparison between data and theory for the total cross section to show that $m_c = 1.3$ GeV is a reasonable choice, and to estimate the range of cross sections, related to the approximate uncertainty in the flux. To evaluate $Z_{pc}$, we need the energy distribution of the charmed particle. In the next section, we discuss the energy distribution of charm quarks in NLO QCD.

### B. Charm Energy Distribution

NLO single differential distributions in charm quark production have been evaluated Nason, Dawson and Ellis [41] and incorporated into a computer program, which also calculates double differential distributions, by Mangano, Nason and Ridolfi [42]. The program is time consuming, so we have incorporated NLO corrections to $d\sigma/dx_E$ by rescaling the leading order distribution. The $x_E$ distributions at next-to-leading order are well fit by a $K$-factor rescaling which is a function of $x_E$, where $K$ is defined by

$$K \equiv \frac{d\sigma(NLO)/dx_E}{d\sigma("LO")/dx_E}$$

where "LO" means taking the leading order matrix element squared, but using the two-loop $\alpha_s(\mu^2)$ and the NLO parton distribution functions. $K$ defined this way shows the effects of the NLO matrix element corrections.

Using the NLO computer program with the CTEQ3 parton distribution functions, we show our results for $K(E, x_E)$ for $E = 10^3$ and $2K(E, x_E)$ for $E = 10^6$ GeV in Fig. 3. We find that $K$ evaluated using the D- and MRSA distributions agree well with Fig. 3. The error bars indicate the numerical errors associated with the Monte Carlo integration in the
NLO program. At higher energies, the errors become larger for comparable $x_E$ because the cross section is dominated by small $x_E$. $K$ can be parameterized as

$$K(E, x_E) = 1.36 + 0.42 \ln(\ln(E/\text{GeV}))$$

$$+ \left(3.40 + 18.7(E/\text{GeV})^{-0.43} - 0.079 \ln(E/\text{GeV})\right) \cdot x_E^{1.5}$$

(3.4)

for $\mu = m_c$ and $M = 2m_c$. The parameterization is shown by the curves in the figure.

Using the $x_E$ and energy dependent $K$-factor, we plot the charm quark $x_E$ distribution for $E = 10^3 \text{ GeV}$, $10^6 \text{ GeV}$ and $10^9 \text{ GeV}$ in Fig. 4. The distributions fall rapidly with $x_E$. The convolution of the differential distribution with the ratio of proton fluxes and interaction lengths, integrated over $x_E$ at fixed outgoing charm quark energy, is what is required for the $Z$-moment.

Fig. 5 shows the differential moment, $dZ_{pc}/dx_E$. The solid lines are for CTEQ3 distributions at outgoing charm energies $E = 10^4 \text{ GeV}$, $10^6 \text{ GeV}$ and $10^8 \text{ GeV}$, in increasing magnitudes. The dashed lines represent the same quantities for the D- calculation. The D-distributions have approximately the same shape as the CTEQ3 distributions, but there is a more rapid growth in overall normalization with energy.

In the context of perturbative hard scattering production of charm pairs, the average $x_E$ value in the evaluation of $Z_{pc}$ is 0.15-0.2. More than 80% of the cross section comes from charm transverse momenta below a value of $2m_c$. In the low transverse momentum limit, $x_E \simeq x_F$. Fixed target experiments measure $d\sigma/dx_F$. The measured charmed meson $x_F$ distributions are consistent with the perturbative NLO QCD calculations for charm quark production, without any fragmentation corrections that would soften the $x_F$ distributions [43]. Fragmentation calculations are applicable at large transverse momentum. For the calculation of $Z_{pc}$, we are in the low transverse momentum regime, so we do not need fragmentation.

C. Hadron Fractions

We account for the transformation of charmed quarks into hadrons by an energy independent hadronic fractions. The hadronic fractions convert $Z_{pc}$ into the interaction moments for the charmed mesons and the $\Lambda_c$ via Eq. (2.11). The hadron fractions can be obtained by the observation that [33][44]

$$\sigma(D_s) \simeq 0.2 \sigma(D^0 + D^+)$$

(3.5)

$$\sigma(\Lambda_c) \simeq 0.3 \sigma(D^0 + D^+)$$

(3.6)

The fractions of charmed quarks that appear as $D_s$ and $\Lambda_c$ are

$$f_{D_s} = 0.13$$

(3.7)

$$f_{\Lambda_c} = 0.20$$

(3.8)

To get the $D^+$ and $D^0$ fractions, one needs a ratio of $\sigma(D^+)/\sigma(D^0)$. Using arguments based on isospin invariance and counting of states in the production of $D$ and $D^*$, together with branching fractions for $D^* \rightarrow D$, Frixione et al. [33] suggest that $\sigma(D^+)/\sigma(D^0) \simeq 0.32$. With this assumption for the ratio of the cross sections,
There is some uncertainty in the values of $f_j$. Experimental measurements of $\sigma(D^+)/\sigma(D^0)$ in pN and pp fixed target experiments tend to lead to a somewhat higher ratio of cross sections. For example in pp collisions with a beam energy of $E_b = 400$ GeV, the LEBC-EHS Collaboration [45] measures $\sigma(D^+)/\sigma(D^0) = 0.7 \pm 0.1$, while in pN collisions at $E_b = 250$ GeV, the ratio is measured by E769 [46] to be $0.57 \pm 0.22$. By taking $\sigma(D^+)/\sigma(D^0) = 0.6$, the resulting change in the predicted flux is only $\sim 15\%$.

Integrated Z-moment $Z_{pD^0}$ scaled by $10^3$ versus charmed particle energy is shown in Fig. 6 for the D- and CTEQ3 distributions with $\mu = m_c$ and $M = 2m_c$. Also shown is the CTEQ3 calculation with $\mu = M = m_c$. The other Z-moments for charm production are simple rescalings of Fig. 6. While the curves are similar up to 1 TeV, by $E = 10^6$ GeV, there is a factor of $\sim 5$ between the upper and lower curves. At $E = 10^8$ GeV, the upper and lower curves differ by more than a factor of 10, larger than the ratio of cross sections at the same energy. This is accounted for by the fact that the Z-moments at energy $E$ involve integrals of the cross section at a higher energy. In addition, since $x_E \sim 0.15 - 0.2$ and the cross section is dominated by parton invariant masses near $m_c$, small parton $x$ values are emphasized. Since the prompt flux is proportional to $Z_{pc}$, this enhancement is reflected in the flux as well.

D. Decay Moments

The last elements of the calculation of the lepton fluxes from charm are the decay moments $Z_{kl}(E)$ for $k = D^+, D^0, D^+_s$ and $\Lambda_c$. The decay moments can be written in the same form as Eq. (2.4) with $\lambda_k$ now representing the decay length. The decay distribution can be represented by

$$
\frac{dn_{k\to \ell}(E; E_k)}{dE} = \frac{1}{E_k} F_{k\to \ell} \left( \frac{E}{E_k} \right),
$$

so the decay moments, in terms of an integral over $x_E = E/E_k$, are

$$
Z_{kl}(E) = \int dx_E \frac{\phi_k(E/x_E)}{\phi_k(E)} F_{k\to \ell}(x_E).
$$

The function $F$ is given in Ref. [20,17], in the approximation that the leptonic decays of charmed mesons are approximated by three-body decays. In the ultrarelativistic limit, $F$ is nearly equal for $\ell = \nu_e, \nu_\mu$ and $\mu$, so the decay moments for the three leptons are essentially equal. Consequently, we take the fluxes for the three leptons to be equal.

Following Bugaev et al. in Ref. [17], the effective hadronic invariant mass $m_X$ of the decay of the $D^+$ is taken to be 630 MeV and for the $D^0$ decays, 670 MeV. We take $m_X = 840$ MeV for $D_s$ decays. The $\Lambda_c$ will ultimately contribute little over most of the energy range considered. For $\Lambda_c$ decays, we use the same three-body formula with an effective hadronic mass of 1.3 GeV. The branching ratios are:

$$
f_{D^0} = 0.51 ,
$$

$$
f_{D^+} = 0.16 .
$$
\[ B(D^+ \to \ell) = 17\% , \]
\[ B(D^0 \to \ell) = 6.8\% , \]
\[ B(D_s \to \ell) = 5.2\% , \]
\[ B(\Lambda_c \to \ell) = 4.5\% . \]

For the energies considered here, the charmed particle fluxes in the low energy limit dominate. Assuming that \( Z_{pp} \) and \( \Lambda_p \) are nearly energy independent, this means that
\[ \phi_k \sim Z_{pk}(E) E \phi_p(E) . \]

The proton flux falls like \( E^{-2.7} \) – \( E^{-3} \). The charm production \( Z \)-moments increase with energy, as seen in Fig. 6. When we put in the low energy \( D^+ \) meson flux and evaluate the \( Z_{D^+\ell} \) moment, we get the results shown in Fig. 7. All of the other low energy decay moments can be obtained by branching fraction rescaling. For the high energy moments, we take \( Z_{pk} \sim E^{0.42} \) for the \( D^- \) distributions and \( Z_{pk} \sim E^{0.23} \) for CTEQ3, with \( \phi_k \sim Z_{pk}(E) \phi_p(E) \).

**IV. PROMPT LEPTON FLUX**

In Fig. 8 we show our results for the prompt atmospheric flux scaled by \( E^3 \) for two parton distributions and factorization scale choices. The highest flux at \( E = 10^8 \) GeV is with the \( D^- \) distribution and \( M = 2\mu = 2m_c \) (dashed). The CTEQ3 distributions with the same choice of scale are represented by the solid line, while the dot-dashed line shows the result when \( M = \mu = m_c \). For reference, we show the vertical conventional and prompt flux calculated and parameterized by TIG in Ref. [14]. The fluxes directly reflect the interaction \( Z \)-moments of Fig. 6. We emphasize that the prompt flux is isotropic except at the highest energies, while the conventional flux is not.

We have also estimated the flux due to pion-air interactions creating charm pairs. The effect is to increase the prompt flux by \( \sim 30\% \) at \( 10^2 \) GeV and by \( \sim 15\% \) at \( 10^6 \) GeV. This is a small effect, so we neglect pion contributions to charm production.

The prompt lepton flux evaluated using perturbative QCD can be parameterized as
\[ \log_{10} \left( E^3 \phi_\ell(E)/(\text{GeV}^2/\text{cm}^2/\text{s sr}) \right) = -A + B x + C x^2 - D x^3 \]
where \( x \equiv \log_{10}(E/\text{GeV}) \). In Table I, we collect the constants for the \( D^- \) and CTEQ3 fluxes exhibited in Fig. 8.

The TIG flux relies on PYTHIA calculations with \( m_c = 1.35 \) GeV and the MRSG [37] parton distribution functions. For \( E < 1 \) TeV, the TIG flux is larger than ours because of fragmentation effects. Their calculation uses the Lund hadronization model [17] which can give the charmed hadron a larger energy than the charmed quark, an effect which is larger for smaller center of mass energies. The TIG prompt flux calculation is lower than our calculation for energies \( E > 1 \) TeV. At parton \( x < 10^{-4} \), the parton distributions in the TIG calculation are flattened. For example, the gluon distribution is
\[ x g(x, Q) \sim x^{-0.08} \]
below \( x = 10^{-4} \). We note that HERA data at \( 10^{-5} < x \) and \( Q_0 \sim 2 \) GeV show no indication of flattening [29]. NLO effects in the TIG calculation are accounted for by an energy and
$x_E$ independent factor of 2. Overall, the net effect is that the TIG $Z_{pe}$ is nearly energy independent.

The prompt muon flux by Volkova et al. [13] is larger than our calculated flux. This comes in part because of their assumption that $d\sigma/dx_E \sim (1 - x_E)^5/x_E$, independent of center of mass energy and a cross section larger than the perturbative one below $E \sim 10^5$ GeV. This $x_E$ dependence is harder than the perturbative $x_E$ dependence shown in Fig. 4.

Bugaev et al. [17] have presented calculations of the prompt muon flux using two phenomenological, nonperturbative approaches. One is based on the Recombination Quark-Parton Model (RQPM) and the other on the Quark-Gluon String Model (QGSM). The QGSM prompt flux is relatively small compared to the RQPM flux, which already affects the total atmospheric muon flux at energies of a few tens of TeV. Relative to the RQPM calculation and the Volkova et al. results, our D-prompt flux is lower.

Several experiments show an excess in muon flux above $\sim 10$ TeV [7–9]. Following Rhode in Ref. [7], we plot in Fig. 9 the quantity $E_{65}^{3.65} \phi_{\mu}(E)$, where $\phi_{\mu}$ represents the sum of the prompt and vertical conventional flux. Also shown are the data from Ref. [4]. The energy scale factor mostly accounts for the rapidly falling conventional flux [48]. When we add the prompt fluxes of Fig. 8 to the TIG vertical conventional flux, one sees an enhancement at muon energies above $10^5$ GeV, at a higher energy than the experimental excess shown by data points.

In Ref. [49], we have shown that it is possible to enhance the prompt flux sufficiently to account for some of the observed muon excess at a few TeV. This is accomplished by extrapolating the charm cross section at 1 TeV with a faster growth in energy than predicted by perturbative QCD. The $x_E$ dependence was taken as $d\sigma/dx_E \sim (1 - x_E)^4$. The inputs are consistent with fixed target data below 1 TeV beam energies. We found that the predicted prompt flux made significant contributions in the region of the observed excess of muons, but it does not fully describe the Fréjus data [4]. These inputs are not consistent with perturbative QCD. The experimental excess of muons cannot be accounted for by perturbative QCD production of charm.

Another implication of the prompt fluxes calculated here is the ratio of the muon neutrino to electron neutrino flux. We define

$$R_{\theta} = \frac{\phi_{\nu_{\mu}}}{\phi_{\nu_e}}. \quad (4.3)$$

Using the TIG parameterization of the vertical $\theta = 0^\circ$ neutrino fluxes, adding conventional and prompt contributions, $R_0$ as a function of energy is shown in Fig. 10. At a zenith angle of 60°, the conventional flux is a factor of two larger. The ratio $R_{60}$ is also shown in Fig. 10. The quantity $R$ is an interesting diagnostic for the onset of prompt neutrino dominance. Unfortunately, at these energies, $R$ is difficult to measure.

V. CONCLUSIONS

We find that the perturbative charm contributions to lepton fluxes are significantly larger than the recent TIG calculation. The prompt muon flux becomes larger than the conventional muon flux from pion and kaon decays at energies above $\sim 10^5$ GeV. We set values of the charmed quark mass, renormalization scale and factorization scale by fitting the charm

10
production cross section to low-energy data, then we extrapolate to higher energies. We
find that the NLO corrections give a correction of more than a factor of two which is weakly
energy and $x_E$ dependent. Nuclear shadowing corrections are small for all energies, due to
the air nucleus being relatively light. The main uncertainty in the perturbative calculation
of the prompt flux, given fixed charm mass, factorization scale and renormalization scale,
is the small-$x$ behavior of the parton distribution functions. Different choices of scales and
distribution functions, extrapolated to low $x$ with the same power law dependence as for
$x > 10^{-5}$, yield as much as a factor of $\sim 10$ discrepancy in the prompt flux at $E = 10^8$ GeV.

If the parton distributions are flattened below some critical value $x < x_c$ according to Eq.
(4.2), our curves in Fig. 8 would overestimate the lepton fluxes. For example, if $x_c = 10^{-5}$,
the calculated prompt flux at $E = 10^6$ GeV, using CTEQ3 with $M = 2\mu = 2m_c$, is $\sim 80$
of the value shown by the solid curve in Fig. 8, reducing to $\sim 40\%$ of the value at $10^8$ GeV.
For $x_c = 10^{-6}$, the flux is $\sim 70\%$ of our calculated value at $10^8$ GeV. However, such an
abrupt turnover in the power law behavior of the small-$x$ parton distributions is unlikely.

We conclude that the prompt muon flux calculated in the context of perturbative QCD
cannot explain the observed excess of muons in the TeV region [7–9], independent of the
theoretical uncertainties associated with small parton $x$. However, prompt fluxes calculated
using non-perturbative models of charm production such as discussed in Refs. [17,49] could
provide a muon excess in that energy range. Measurements of the atmospheric flux in
the 100 TeV range would help pin down the charm cross section at energies above those
currently accessible using accelerators and would provide valuable information about the
small-$x$ behavior of the gluon distribution function.

Even though the prompt contributions to the lepton fluxes change the energy behavior of
the differential fluxes by a factor of $E$, the atmospheric neutrino fluxes do not compete with
neutrino fluxes from extragalactic sources above 10 TeV [51]. Possible oscillations of muon
neutrinos as indicated by the Super-Kamiokande experiment [5] do not affect our results
due to the extremely small oscillation probability for the energies of interest.

TABLE I. Parameters for the prompt muon plus antimuon flux appearing in Fig. 8: 
\[ \log_{10}(E^3\phi_\mu/(\text{GeV}^2/\text{cm}^2\text{s sr})) = -A + B x + C x^2 - D x^3, \]
where \( x \equiv \log_{10}(E/\text{GeV}) \).

| PDF  | Scales       | \( A \)  | \( B \)  | \( C \)  | \( D \)  |
|------|--------------|----------|----------|----------|----------|
| CTEQ3 | \( M = \mu = m_c \) | 5.37     | 0.0191   | 0.156    | 0.0153   |
| CTEQ3 | \( M = 2\mu = 2m_c \) | 5.79     | 0.345    | 0.105    | 0.0127   |
| D-    | \( M = 2\mu = 2m_c \) | 5.91     | 0.290    | 0.143    | 0.0147   |
FIG. 1. The NLO $c\bar{c}$ production cross section in $pN$ collisions versus beam energy for $m_c = 1.3$ and 1.5 GeV. The CTEQ3 parton distribution functions are used with $M = \mu = m_c$. The data are taken from the summary in Ref. [28].

FIG. 2. A plot of NLO $\sigma_{pN}^{c\bar{c}}$ versus beam energy for $m_c = 1.3$ GeV using the CTEQ3 (solid) and D- (dashed) parton distribution functions with $M = 2m_c$ and $\mu = m_c$. Also show is the CTEQ3 NLO prediction with $M = \mu = m_c$ (dot-dashed). The data are the same that appear in Fig. 1.
FIG. 3. The function $K(E, x_E)$ defined in Eq. (3.3) versus $x_E$ for $E = 10^3$ GeV and $10^6$ GeV. The points come from the evaluation of $K$ using the results of Ref. [41,42] with error bars indicating numerical errors in the integration, and the curves are our fit to the ratio parameterized in Eq. (3.4).

FIG. 4. For $E = 10^3$ (solid), $10^6$ (dashed) and $10^9$ GeV (dot-dashed), $d\sigma/dx_E$, including the factor of $K(E, x_E)$. The scales used are $\mu = m_c$ and $M = 2m_c$, for $m_c=1.3$ GeV.
FIG. 5. For energies $E = 10^4$ GeV, $10^6$ GeV and $10^8$ GeV, $dZ_{pc}(E)/dx_E$ versus $x_E$ for CTEQ3 (solid) and D- (dashed) parton distribution functions, where $\mu = m_c$ and $M = 2m_c$.

FIG. 6. $Z_{pD0} \times 10^3$ versus $E$ for CTEQ3 (solid) and D- (dashed) parton distribution functions with $\mu = m_c$ and $M = 2m_c$. Also shown is $Z_{pD0} \times 10^3$ for CTEQ3 with $\mu = M = m_c$ (dot-dashed).
FIG. 7. The decay moment for low energy $D^+ \to \ell$ versus energy for D- (dashed) and CTEQ3 (solid) with $M = 2\mu = 2m_c$ and for CTEQ3 with $M = \mu = m_c$ (dot-dashed). The dotted line indicates the decay moment if $Z_{pc}$ is taken independent of energy.

FIG. 8. The prompt atmospheric muon flux scaled by $E^3$ versus muon energy for CTEQ3 (solid) and D- (dashed) with $M = 2\mu = 2m_c$. Also shown is the scaled muon flux using CTEQ3 with $M = \mu = m_c$ (dot-dashed) and the TIG parameterization of the prompt muon flux and the vertical conventional muon flux (dotted).
FIG. 9. The prompt plus vertical conventional atmospheric muon flux scaled by $E^{3.65}$ versus muon energy for CTEQ3 (solid) and D- (dashed) with $M = 2\mu = 2m_c$. Also shown is the scaled muon flux using CTEQ3 with $M = \mu = m_c$ (dot-dashed) and the TIG parameterization of vertical conventional muon flux (dotted). The data shown are from Ref. [7].

FIG. 10. $R = \phi_{\nu_\mu}/\phi_{\nu_e}$ for zenith angles 0° and 60° versus neutrino energy for CTEQ3 (solid) and D- (dashed) with $M = 2\mu = 2m_c$, and using CTEQ3 with $M = \mu = m_c$ (dot-dashed).
