Multiparty Quantum Communication Complexity

Harry Buhrman∗ Wim van Dam† Peter Høyer‡ Alain Tapp§

March 31, 1999

Abstract
Quantum entanglement cannot be used to achieve direct communication between remote parties, but it can reduce the communication needed for some problems. Let each of \( k \) parties hold some partial input data to some fixed \( k \)-variable function \( f \). The communication complexity of \( f \) is the minimum number of classical bits required to be broadcasted for every party to know the value of \( f \) on their inputs.

We construct a function \( G \) such that for the one-round communication model and three parties, \( G \) can be computed with \( n + 1 \) bits of communication when the parties share prior entanglement. We then show that without entangled particles, the one-round communication complexity of \( G \) is \((3/2)n + 1\). Next we generalize this function to a function \( F \). We show that if the parties share prior quantum entanglement, then the communication complexity of \( F \) is exactly \( k \). We also show that if no entangled particles are provided, then the communication complexity of \( F \) is roughly \( k \log_2 k \).

These two results prove for the first time communication complexity separations better than a constant number of bits.

1 Introduction

Suppose each of \( k \) parties holds some data that is unknown to the others, and they want to evaluate some fixed \( k \)-variable function on those data. If the function is non-trivial, then this cannot be done unless the parties communicate.

In [1], Cleve and Buhrman raised the question whether or not less communication is needed if the parties possess entangled particles. They demonstrated that, for a specific problem, prior quantum entanglement decreases the need for communication by 1 bit from 3 to 2 bits. A 1-bit saving was also obtained by Buhrman, Cleve, and van Dam in [3] for another problem where each party initially holds a 2-bit input-string. In both of these problems, there are 3 parties (\( k = 3 \)). They left open the important question if a separation larger than 1 bit is possible. In particular, is a separation in an asymptotic setting possible? In this article we show that this is indeed the case.

Let \( f \) be a \( k \)-variable Boolean function whose inputs are \( n \)-bit binary strings (that is, \( f : X^k \to \{0, 1\} \) where \( X = \{0, 1\}^n \)). There are \( k \) parties, denoted \( P_1, \ldots, P_k \), where party \( P_i \) holds input data \( x_i \) \((i = 1, \ldots, k)\). Initially, party \( P_i \) only knows \( x_i \), so, to evaluate \( f \), the parties have to communicate among each other. The communication is done by broadcasting classical bits, where, each time, a party broadcasts one bit to everybody, on the total cost of one bit of communication.

We are interested in determining the minimum number of bits required to be broadcasted in the worst-case for every party to know the value of $f$. This number is called the communication complexity of $f$ and is denoted $C(f, k, n)$. We want to compare this number with $Q(f, k, n)$, the communication complexity of $f$ with prior quantum entanglement. That is, the situation where we allow the parties to share a set of entangled particles before they learn their inputs $1, 2$.

For example, with this terminology, the separation obtained in $3$ reads: there exists a 3-variable ($k = 3$) Boolean function $g$ whose inputs are 2-bit strings ($n = 2$), and for which $C(g, 3, 2) = 3$, but $Q(g, 3, 2) = 2$. For some functions, no separation at all is possible. For example, Cleve et al. $3$ showed that prior quantum entanglement does not help in computing the so-called inner product function.

References $1, 2$ left open the very interesting question if a separation in an asymptotic setting is possible. This question can be phrased more formal as: Does there exists a function $f$ for which $C(f, k, n)$ grows in $k$ or $n$, and for which the ratio between $C(f, k, n)$ and $Q(f, k, n)$ is bounded from below by some constant larger than 1?

In this paper, we first study the case where the number of parties is three ($k = 3$). In this setting we consider the one-round communication model where each party is allowed to communicate at most once. We construct a Boolean function $G$ for which $C(G, 3, n) = (3/2)n + 1$ whereas $Q(G, 3, n) = n + 1$. This gives a separation by a factor of $3/2$ in terms of the number of bits hold by each of the three parties.

Next we relax the requirement that only one round of communication is allowed and consider an arbitrary number of parties. To this end we generalize the communication function $G$ to $F$. We demonstrate that the communication complexity of $F$ with prior quantum entanglement is exactly $k$ [that is, $Q(F, k, n) = k$], but that, if $n \geq \log_2 k$, then without quantum entanglement it is roughly $k \log_2 k$ [that is, $C(F, k, n) \approx k \log_2 k$]. We prove this by giving upper and lower bounds in both cases. This implies a separation by a logarithmic factor in $k$, the number of parties.

This paper thus presents a function with a separation by a constant factor in terms of the number of bits, and a function with a separation by a logarithmic factor in terms of the number of parties. Very recently, much more impressive separations have been obtained in terms of the number of bits. Buhrman, Cleve, and Wigerson $4$, Ambainis et al. $5$, and Raz $6$ have all found two-party computational problems for which an exponential separation holds.

## 2 The Modulo-4 Sum Problem

In this section, we fix the number of parties to three ($k = 3$). As common, we name the parties Alice, Bob, and Carol.

In $2$, Buhrman, Cleve, and van Dam considered the Modulo-4 Sum Problem defined as follows. Alice, Bob, and Carol receive $x$, $y$, and $z$, respectively, where $x, y, z \in U = \{0, 1, 2, 3\}$, and they are promised that

$$(x + y + z) \mod 2 = 0. \tag{1}$$

The common goal is for every party to learn the value of the function

$$f(x, y, z) = \frac{1}{2} \left[ (x + y + z) \mod 4 \right]. \tag{2}$$

We say that $(x, y, z) \in U \times U \times U$ is a valid input if Eq. $1$ holds. The function $f : U \times U \times U \rightarrow \{0, 1\}$ can be viewed as computing the second-least significant bit in the sum of $x$, $y$, and $z$. Note that for all inputs $y, z \in U$ to Bob and Carol, there exists a unique input $x \in U$ for Alice such that $(x, y, z)$ is a valid input and $f(x, y, z) = 1$.

For every integer $m \geq 1$, we generalize $f$ to $G_m : U^m \times U^m \times U^m \rightarrow \{0, 1\}$ by setting

$$G_m(x, y, z) = 1 \quad \text{if and only if} \quad \text{for all} \ 1 \leq i \leq m \ \text{we have} \ f(x_i, y_i, z_i) = 1,$$

where $x = (x_1, \ldots, x_m)$, $y = (y_1, \ldots, y_m)$, and $z = (z_1, \ldots, z_m)$, and with the condition that,

$$(x_i + y_i + z_i) \mod 2 = 0 \quad (1 \leq i \leq m). \tag{3}$$
Thus, we give Alice, Bob, and Carol \( m \) valid instances of \( f \), all at the same time, and ask if they all evaluate to 1. Again, we say that \((x, y, z)\) is a valid input if Eq. 2 holds.

Buhrman et al. [3] showed that with prior entanglement, function \( f \) can be solved with one-round communication using 3 bits. In their protocol, Bob and Carol each broadcast one bit, where after Alice is capable of computing the value of \( f \) and then broadcasting the resulting bit. (See Section 2.1 for a direct generalization of their protocol.) Their protocol therefore immediately yields a \( 2m + 1 \) bits protocol for \( G_m \).

**Theorem 1** With prior quantum entanglement \( G_m \) can be solved with one-round communication using \( 2m + 1 \) bits.

In Subsection 2.2 below, we prove the following lower bound for the case that we do not allow quantum entanglement.

**Theorem 2** Without quantum entanglement, there is no one-round protocol for \( G_m \) that uses less than \( 3m + 1 \) bits of communication.

For one-round protocols we thus archive a separation of \( 2m + 1 \) bits against \( 3m + 1 \) bits. We do not know the classical communication complexity of computing \( G_m \) without any restriction on the number of rounds.

### 2.1 Classical Upper Bound

The lower bound in Theorem 2 is tight as there is a straightforward one-round protocol that computes \( G_m \) with \( 3m + 1 \) bits of communication. It is instructive for understanding the proof of our lower bound, first to understand that protocol.

Consider an input \( x \in U^m \) to Alice. We can think of \( x = (x_1, \ldots, x_m) \) as consisting of two parts, the high bits and the low bits. That is, we identify \( x \) with the pair \((x_{\text{high}}, x_{\text{low}})\), where the \( i \)-th coordinate in \( x_{\text{high}} \in \{0, 1\}^m \) is \((x_i \text{ div } 2)\), and where the \( i \)-th coordinate in \( x_{\text{low}} \in \{0, 1\}^m \) is \((x_i \mod 2)\). We think of Bob’s input \( y = (y_1, \ldots, y_m) \) and Carol’s input \( z = (z_1, \ldots, z_m) \) in a similar manner.

The \( 3m + 1 \) one-round protocol works as follows: First Bob broadcasts all \( 2m \) bits of his input \((y_{\text{high}}, y_{\text{low}})\). Then Carol broadcasts the \( m \) high bits \( z_{\text{high}} \) of her input. Now Alice is capable of computing the value of \( f \) on all \( m \) instances, that is, she can compute \( f(x_i, y_i, z_i) \) for all \( 1 \leq i \leq m \). Due to the promise that \((x_i + y_i + z_i) \mod 2 = 0\), she does not need the low bits \( z_{\text{low}} \) of Carol’s input. Finally Alice checks if \( f(x_i, y_i, z_i) = 1 \) for all \( 1 \leq i \leq m \). If so, \( G_m(x, y, z) = 1 \) and Alice therefore broadcasts 1, otherwise she broadcasts 0.

Intuitively, Alice has to have all of Bob’s \( m \) high bits, all of Carol’s \( m \) high bits, but just \( m \) of the \( 2m \) low bits. Hence, intuitively, if there exists a protocol for \( G_m \) in which Bob broadcasts \( s_B \) bits and Carol broadcasts \( s_C \) bits, then \( s_B \) should be at least \( m \), \( s_C \) at least \( m \), and \( s_B + s_C \) at least \( 3m \). It is the result of the following subsection that this intuition is valid.

### 2.2 Classical Lower Bound

We now prove our lower bound stated in Theorem 2. Since we only consider one-round protocols, we can without loss of generality assume that any protocol computing \( G_m \) is made up of the following three parts:

1. Bob (knowing only his input \( y \)) broadcasts the message \( \sigma_B = \sigma_B(y) \).
2. Carol (knowing her input \( z \) and Bob’s message \( \sigma_B \)) broadcasts the message \( \sigma_C = \sigma_C(z, \sigma_B) \).
3. Alice (knowing \( x, \sigma_B, \) and \( \sigma_C \)) computes the answer \( \sigma_A(x, \sigma_B, \sigma_C) \in \{0, 1\} \) which she then broadcasts to Bob and Carol. Since this protocol computes \( G_m \), we can without loss of generality assume that \( \sigma_A = G_m \) on all valid inputs.
In agreement with our intuition described above, the following key lemma explicitly specifies $2^m$ different inputs on which Bob and/or Carol have to send different messages. Theorem 2 is immediate.

**Lemma 1** Consider the above one-round protocol for computing $G_m$. Let $\sigma_B$ and $\sigma_C$ denote Bob’s and Carol’s messages on inputs $y = (y_{\text{high}}, y_{\text{low}})$ and $z = (z_{\text{high}}, y_{\text{low}})$, respectively. Let $\sigma_B'$ and $\sigma_C'$ denote Bob’s and Carol’s messages on inputs $y' = (y_{\text{high}}, y'_{\text{low}})$ and $z' = (z'_{\text{high}}, y'_{\text{low}})$, respectively. Then the following holds.

1. If $y_{\text{high}} \neq y'_{\text{high}}$ and $y_{\text{low}} = y'_{\text{low}}$, then $\sigma_B \neq \sigma_B'$.
2. If $z_{\text{high}} \neq z'_{\text{high}}$ and $y_{\text{low}} = y'_{\text{low}}$, then $\sigma_C \neq \sigma_C'$.
3. If $y_{\text{low}} \neq y'_{\text{low}}$, then $\sigma_B \neq \sigma_B'$ or $\sigma_C \neq \sigma_C'$.

We first prove (i) by contradiction. Assume $y_{\text{high}} \neq y'_{\text{high}}$, $y_{\text{low}} = y'_{\text{low}}$, and $\sigma_B = \sigma_B'$. Let $x$ be the unique input to Alice such that $G_m(x, y, z) = 1$. Then $(x, y', z) = (x, (y'_{\text{high}}, y_{\text{low}}), z)$ is a valid input on which $G_m$ takes the value 0. But, since $\sigma_B = \sigma_B'$, we also have $\sigma_C(z, \sigma_B) = \sigma_C(z, \sigma_B')$, and hence Alice incorrectly outputs the same answer $\sigma_A(x, \sigma_B, \sigma_C) = \sigma_A(x, \sigma_B', \sigma_C')$ in both cases. Thus, the assumption is wrong and (i) holds.

The proof of (ii) is almost identical to the proof of (i), and we therefore omit it.

We also prove (iii) by contradiction. Assume $y_{\text{low}} \neq y'_{\text{low}}$, $\sigma_B = \sigma_B'$, and $\sigma_C = \sigma_C'$. Let $x = (x_{\text{high}}, 0)$ be the unique input to Alice such that $G_m(x, y, z) = 1$. Since the protocol correctly computes $G_m$, then Alice must answer 1 on the input $(x, y, z)$. But then $(x, y', z')$ is also a valid input on which Alice answers 1. Further, let $x' = (x'_{\text{high}}, x_{\text{low}})$ be the unique input to Alice such that $G_m(x', y', z) = 1$. Since the protocol correctly computes $G_m$, then Alice must answer 1 on the input $(x', y', z)$. But then $(x', y, z')$ is also a valid input on which Alice answers 1.

Thus, Alice answers 1 on all of these 4 valid inputs: $(x, y, z)$, $(x, y', z')$, $(x', y', z)$, and $(x', y, z')$. But, since $y_{\text{low}} \neq y'_{\text{low}}$, then (as we show in the next paragraph) $G_m$ takes the value 0 on at least one of the valid inputs $(x, y', z')$ and $(x', y, z')$, and thus the protocol incorrectly computes $G_m$. Hence, the assumption is wrong and (iii) follows.

To see that $G_m$ has to take the value 0 on at least one of the valid inputs $(x, y', z')$ and $(x', y, z')$, assume otherwise. Let $1 \leq i \leq m$ be a coordinate where $y_{\text{low}}$ and $y'_{\text{low}}$ differ. For ease of notation, we let $y_{\text{low}}$ denote the $i$-th coordinate (bit) of $y_{\text{low}} \in \{0, 1\}^m$, and we use similar notation for the $i$-th coordinate of the other vectors.

- Since $G_m(x, y, z) = 1$, then $(x_{\text{high}} + y_{\text{high}} + z_{\text{high}} + y_{\text{low}}) \mod 2 = 0$.
- Since $G_m(x', y', z) = 1$, then $(x'_{\text{high}} + y'_{\text{high}} + z_{\text{high}} + y'_{\text{low}}) \mod 2 = 0$.
- Since $G_m(x, y', z') = 1$, then $(x_{\text{high}} + y'_{\text{high}} + z'_{\text{high}} + y_{\text{low}}) \mod 2 = 0$.
- Since $G_m(x', y, z') = 1$, then $(x'_{\text{high}} + y_{\text{high}} + z'_{\text{high}} + y'_{\text{low}}) \mod 2 = 0$.

But all of these 4 equations cannot hold at the same time, and thus the assumption that $G_m$ takes the value 1 on $(x, y', z')$ and $(x', y, z')$ is wrong. This completes our proof of Lemma 1, from which Theorem 2 immediately follows.

It is worthy noticing that, by Lemma 1, for Alice to correctly output the value of $G_m$, she has to be able to correctly compute $f$ on every one of the $m$ instances of $f$. This is in general not so, and it is a deep open question in communication complexity to characterize the functions that possess this property.

### 3 Multi-Rounds and Parties

We now generalize $f$ defined in Eq. 3 to a function $F$ which we shall use to prove a separation in terms of the number of parties. There are $k$ parties, where party $P_i$ obtains input data $x_i \in V = \cdots$
\{0, \ldots, 2^n - 1\} (i = 1, \ldots, k). We say that an input \( \mathbf{x} = (x_1, \ldots, x_k) \) is valid if it satisfies that
\[
\left( \sum_{i=1}^{k} x_i \right) \mod 2^{n-1} = 0. \tag{4}
\]
Let \( F : V^n \rightarrow \{0, 1\} \) denote the Boolean function on the valid inputs defined by
\[
F(\mathbf{x}) = \frac{1}{2^{n-1}} \left[ \left( \sum_{i=1}^{k} x_i \right) \mod 2^n \right]. \tag{5}
\]
We say that a valid input \( \mathbf{x} \) is \( b \)-valid if \( F(\mathbf{x}) = b \) (\( b = 0, 1 \)). The function \( F \) can be viewed as computing the \( n \)-th least significant bit of the sum of the \( x_i \)'s.
We first show that with prior quantum entanglement, \( k \) bits of communication are necessary and sufficient for every party to evaluate \( F \). That is, for all \( k \geq 2 \) and \( n \geq 1 \),
\[
Q(F, k, n) = k. \tag{6}
\]
Then, we show how the parties can evaluate \( F \) with roughly \( k \log_2 k \) bits of communication without using any entangled particles. Specifically, for all \( k \geq 2 \) and \( n \geq 1 \),
\[
C(F, k, n) \leq (k - 1) \left\lceil \log_2 (k - 1) \right\rceil + 1. \tag{7}
\]
Finally, we prove that this is optimal up to low order terms by showing that, for all \( k \geq 2 \) and \( n \geq \log_2 k \),
\[
C(F, k, n) > k \log_2 (k) - k. \tag{8}
\]
By comparing the bounds of Eqs. \ref{eq:6} and \ref{eq:8}, we see that we have established a separation by a factor of \( \log_2 (k/2) \).

### 3.1 With Entanglement

We first show that if the parties share entangled particles, then in a straight-forward manner, the \( k \) parties can evaluate \( F \) using only one bit of communication each. This is obtained by a direct generalization of the idea used both in Sect. 2.1 of \cite{2} (which itself is based on the work of Mermin \cite{7}) and in \cite{8}. The prior quantum entanglement shared by the \( k \) parties is the cat state \( |q_1 \ldots q_6\rangle = (|0 \ldots 0\rangle + |1 \ldots 1\rangle)/\sqrt{2} \), where party \( P_i \) holds qubit \( q_i \) (\( i = 1, \ldots, k \)).

Each party \( P_i \) uses the following procedure. First party \( P_i \) applies a phase-change operator \( \phi(x_i) \) defined by \( |0\rangle \mapsto |0\rangle \) and \( |1\rangle \mapsto \exp(2\pi i \sqrt{-1}/2^n)|1\rangle \) on her qubit \( q_i \). Thanks to the promise on the inputs, these phase rotations add up so that the resulting state is \( (|0 \ldots 0\rangle + (-1)^{F(\mathbf{x})}|1 \ldots 1\rangle)/\sqrt{2} \). Then she applies the Walsh-Hadamard transform that maps \( |0\rangle \) to \( (|0\rangle + |1\rangle)/\sqrt{2} \), and \( |1\rangle \) to \( (|0\rangle - |1\rangle)/\sqrt{2} \). Finally, she measures her qubit \( q_i \) in the computational basis \( \{|0\rangle, |1\rangle\} \) and broadcasts the outcome bit.

Let \( b_i \) be the outcome of party \( P_i \)’s measurement. Simple calculations show that \( b_1 \oplus \cdots \oplus b_k \) equals \( F(x_1, \ldots, x_k) \), where \( \oplus \) denotes addition in modulo-2 arithmetic. It follows that every party can compute the value of \( F \) from the \( k \) communicated bits. On the other hand, \( k \) bits of communication are necessary since if one of the parties does not broadcast any bits, then none of the others can determine the value of \( F \). To see this, note that if we toggle the most significant bit of any one of the inputs, then the value of \( F \) changes. Equation \ref{eq:8} follows.

### 3.2 Without Entanglement

The simplest way to evaluate the function \( F \) is for all but one of the parties to broadcast their inputs. The last party then evaluates \( F(x_1, \ldots, x_k) \) and communicates the resulting bit to the others. Hence, the communication complexity (without entanglement) is at most \( (k - 1)n + 1 \).
Now, consider that all but one of the parties broadcast the \( d \) most significant bits of their inputs, for some integer \( d \geq 1 \). The last party, say \( P_k \), then computes the sum \( (\sum_{i=1}^{k} x_i) - \delta \) where
\[
\delta = \sum_{i=1}^{k-1} (x_i \mod 2^{n-d}).
\]
Suppose \( n \geq d \) where \( d = 1 + \lceil \log_2 (k - 1) \rceil \). Then
\[
0 \leq \delta \leq (k - 1)(2^{n-d} - 1) < 2^{n-1},
\]
so party \( P_k \) knows the value of the sum \( \sum_{i=1}^{k} x_i \) up to an additional non-negative term strictly smaller than \( 2^{n-1} \). Since the sum is divisible by \( 2^{n-1} \) for all valid inputs, party \( P_k \) can determine it exactly and thus compute the value of \( F \). It follows that \( (k - 1)d + 1 \) bits of communication suffice, as stated as Eq. 7.

A good method to prove lower bounds for the communication complexity of functions comes from a combinatorial view on the protocol for the communication. Consider the space \( V^k \) of all possible inputs, where \( V = \{0, \ldots, 2^n - 1\} \). A \textit{rectangle} in \( V^k \) is a subset \( R \subseteq V^k \) such that \( R = R_1 \times \cdots \times R_k \) for some \( R_i \subseteq V \) \((i = 1, \ldots, k)\). If a rectangle contains no 0-valid inputs or no 1-valid inputs, then it is said to be \( F \)-monochromatic.

We now use the observation that every deterministic and errorless communication protocol corresponds to a covering of all the valid inputs in \( V^k \) by \( F \)-monochromatic rectangles (see [9]). Without increasing the communication complexity, such a protocol can always be transformed into a protocol that uses a partitioning that covers all of \( V^k \), and for which each monochromatic rectangle contains at least one valid input. By proving that every such partition requires at least \( t \) rectangles, we also prove that the communication complexity of \( F \) is at least \( \log_2 t \) [9]. Hence, upper bounds on the cardinality of the possible \( F \)-monochromatic rectangles imply a lower bound on the communication complexity of \( F \).

In the appendix, we prove that if a rectangle \( R \subseteq V^k \) is \( F \)-monochromatic and if \( R \) contains a valid input, then its cardinality is upper bounded by a value \( r \), for which
\[
r = \left( \frac{2^n - 2}{k} + 1 \right)^k.
\]
Since there are \( 2^{nk} \) input values to be covered, this bound on the size of the rectangles shows that we need at least \( t = 2^{nk} / r \) rectangles to partition \( V^k \) in the above described fashion.

If \( n \geq \log_2 k \) and \( k \geq 2 \), then basic algebra gives that
\[
\log_2 t = \log_2 \left( \frac{2^{nk}}{r} \right) > k \log_2 (k) - k.
\]
From this, the lower bound on the communication complexity of Eq. 8 follows.

Foundation research meeting on quantum computation.
Appendix: Upper Bound on the Cardinality of a Monochromatic Rectangle

Equip the set $V = \{0, \ldots, 2^n - 1\}$ with the natural addition operation, denoted $\oplus$ and given by $x \oplus y = (x + y) \mod 2^n$. Then $V = (V, \oplus)$ is a cyclic group of order $2^n$.

Let $R \subseteq V^k$ be a fixed rectangle. By definition, $R = R_1 \times \cdots \times R_k$ for some subsets $R_i \subseteq V$, $i = 1, \ldots, k$. For any two subsets $A, B \subseteq V$, define $A \oplus B = \{a \oplus b \mid a \in A, b \in B\}$. We now define a family of subsets of $V$. Set $S_0 = \{0\} \subset V$ and $S_i = S_{i-1} \oplus R_i$ for $i = 1, \ldots, k$. Then for each element $(x_1, \ldots, x_k) \in R$, the value $(\sum_{i=1}^{k} x_i) \mod 2^n$ is in $S_k$. We shall use Kneser’s theorem \[10\] to give an upper bound on the cardinality of $R$.

Kneser’s theorem Let $G = \langle G, \oplus \rangle$ be an Abelian group with finite subsets $A$ and $B$. Then there exists a subgroup $H$ of $G$ such that

$$A \oplus B \oplus H = A \oplus B$$

and

$$|A \oplus B| \geq |A \oplus H| + |B \oplus H| - |H|.$$ 

Let $H_i$ be the largest subgroup of $V$ for which $S_i = S_i \oplus H_i$, $(i = 0, \ldots, k)$. Since $\oplus$ is associative, then $H_{i-1} \subseteq H_i$ for all $1 \leq i \leq k$.

Suppose $R$ is a monochromatic rectangle that contains a valid input. Without loss of generality, assume that it is a 0-valid input, that is, that $0 \in S_k$. Then $H_i$ is the trivial subgroup $\{0\}$ for all $i$, since otherwise we have that $2^{n-1} \in H_i \subseteq H_k$ and hence $R$ would not be monochromatic. This shows that if we identify $A = S_{i-1}$ and $B = R_i$ in Kneser’s theorem, it follows that $H$ is the trivial subgroup. We therefore have that $|S_i| \geq |S_{i-1}| + |R_i| - 1$, so

$$|S_k| \geq \sum_{i=1}^{k} |R_i| - (k - 1).$$ 

Since $2^{n-1} \not\in S_k$, then $|S_k| \leq 2^n - 1$, so

$$\sum_{i=1}^{k} |R_i| \leq 2^n - 2 + k,$$

and therefore

$$|R| = \prod_{i=1}^{k} |R_i| \leq \left(\frac{2^n - 2}{k} + 1\right)^k.$$ 

It follows that the right hand side of Eq. 8 is an upper bound on the cardinality of any $F$-monochromatic rectangle that contains a valid input.

Corollary 1.17 states the fact for 2 parties only: If every partition of $V^2$ into $f$-monochromatic rectangles requires $t$ or more rectangles, then the communication complexity of $f$ is at least $\log_2 t$. It is an easy exercise to generalize this result to any number of parties ($k \geq 2$). The question of additivity is discussed in section 4.1, open problem 4.2. A lower bound for partial functions via monochromatic rectangles is stated as proposition 5.4 in section 5.
