Featured Application: This work has potential applications for all-fiber electro-optic modulators, all-fiber optical-to-frequency converters and optical switching.

Abstract: Fused silica are common fiber materials which have macroscopic central symmetry without second-order nonlinearity. Studies have shown that thermal poling of fused silica fibers can destroy this macroscopic central symmetry, resulting in second-order nonlinearity or linear electro-optical effects. In this paper, a new type of double-hole optical fiber is designed. A two-dimensional (2D) numerical model is used to simulate the movement of ions and the formation of space charge region by finite element analysis. It is found that the single round square hole structure of the new double-hole fiber promotes the thermal poling process. The effective second-order nonlinear coefficient $\chi^{(2)}_{	ext{eff}}$ of the new double-hole poled fiber is 0.28 pm/V at the core center, which is 0.05 pm/V higher than that of the circular double-hole poled fiber. In the fiber core, the radial distribution of the internal electric field and of $\chi^{(2)}_{	ext{eff}}$ is calculated and analyzed. The results of this paper are of great significance for the application of thermally poled fibers on nonlinear all-fiber devices.

Keywords: new double-hole optical fiber; thermal poling; second-order nonlinearity; finite element analysis

1. Introduction

Thermal poling, a technique to induce second-order nonlinear effects and linear electro-optic effects in the center-symmetric fused silica fiber [1], allows the realization of all-fiber electro-optic modulators, all-fiber optical-to-frequency converters [2], switching [3] and polarization-entangled photon pair generation [4]. Poling temperature and poling voltage are important influence factors of second-order nonlinearity induced in the fiber core [5]. Besides, the poling duration also affects the value of the $\chi^{(2)}_{	ext{eff}}$ [6].

Double anodes were addressed by Margulis et al. [7], who demonstrated that it is possible to avoid electrical breakdown and improve the stability and strength of $\chi^{(2)}_{	ext{eff}}$ induced by thermal poling. To further understand the physical process based on the double anodes model and optimize its poling parameters, Camara studied the microscopic mechanism of ion movement in thermally poled double-hole fibers using COMSOL Multiphysics finite element analysis [8]. The impact of poling parameters (voltage, temperature, initial ionic concentrations, etc.) on the induced $\chi^{(2)}_{	ext{eff}}$ is also analyzed. Recently, a new type of thermal poling technology, electrostatic induction, developed by De Lucia et al., lifts a number of restrictions on the use of complex microstructured optical fibers (MOF) for poling, as it is no longer necessary to individually contact internal electrodes [9].
In this paper, a new type of double-hole fiber is designed, and the thermal poling process of this new double-hole fiber and circular double-hole fiber is analyzed by using COMSOL Multiphysics platform. This model is based on a previously proposed two-dimensional charge dynamics model [10]. In this model, Na\(^+\) ions which are initially uniformly distributed in the fiber and hydrogen-related species (H\(_2\)O\(^+\)) which are injected from electrodes are mainly considered. Different from the circular double-hole electrode structure, the new double-hole electrode structure proposed in this paper is a rectangle with a single rounded edge, and its single rounded edge causes a larger concentration of ions migrating toward the core. Based on this, a simulation model is established to calculate and analyze the migration process of ions inside the fiber and time evolution of the internal electric field on the core. The results show that the \(\chi^{(2)}\) of the new double-hole poled fiber is higher than that of the circular double-hole fiber at a temperature of 285 °C and a voltage of 5 kV.

2. Principle and Model

The poling principle of the model is summarized below. At the beginning of poling, in the high temperature and high voltage condition, sodium (Na\(^+\)) of high mobility is first activated. Driven by the external electric field, sodium (Na\(^+\)) migrates from the anode to the cathode and the outer surface of the fiber. At this time, cation-depleted region is formed on the outer surface of the anode. As thermal poling proceeds, the water molecules in the air at the surface of the anode ionize into H\(_2\)O\(^+\) under the effect of the external electric field, and then accumulate into the fiber. H\(_2\)O\(^+\) of lower mobility also begins to migrate toward the cathode and the outer surface of the fiber, gradually neutralizing the negatively charged holes [11] left by the migration of Na\(^+\). This promotes the process of the depletion region covering the core. When the depletion region covers the fiber core center, the internal electric field reaches a maximum. The maximum electric field is recorded after the bias is switched off and temperature is lowered to room temperature [12]. The optical fiber is initially neutral and maintains this neutrality all along the poling process [13].

The model is based on the COMSOL finite element method of the transport of diluted species problem, assuming that low concentration ions (~1 ppm) move in the presence of diffusion and drift due to an electric field [8]. Both migration and diffusion are taken into account, which can be derived by coupling the local equation of continuity to Poisson’s equation [14]:

\[
\frac{\partial C_i}{\partial t} + \nabla \cdot (D_i \nabla C_i - z_i \mu_i F C_i \nabla \Phi) = R_i + \sum_{i} z_i C_i
\]

where the index i represents different ionic species, \(C_i\) is ionic concentration, \(D_i\) is the diffusivity, \(z_i\) is the charge, \(\mu_i\) is the ionic mobility, \(F\) is Faraday’s constant, \(\Phi\) is the electric potential during poling, and \(R_i\) is the production or consumption rate. \(D_i = k_B T \mu_i / e\), \(k_B\) is the Boltzmann constant, \(T\) is the temperature. The first term in the local equation of continuity explains the transient of the ionic, and the second term explains the drift and diffusion of the charge. The Poisson’s equation shows that the charge distribution determines the electric field distribution. Combined with the equation \(\chi^{(2)} = 3\chi^{(3)} \cdot E_{rec}\), the evolution of second-order nonlinearity of optical fiber by thermal poling can be obtained [15].

The material type used in the simulation for the fibers is silica glass with a refractive index of 1.468. The two models use three modules: electrostatics, transport of diluted species and general form boundary partial differential equation. The electrostatics module mainly sets the electric potential and the space charge density of the fiber, wherein the space charge density changes with the concentration of Na\(^+\) and H\(_2\)O\(^+\). The transport of diluted species module mainly sets the concentration, diffusion coefficient and mobility of Na\(^+\) and H\(_2\)O\(^+\) in the fiber. The general form boundary PDE module sets the concentration of H\(_2\)O\(^+\) at the holes boundary \(\frac{\partial C}{\partial t} = \sigma_2 E\) [13]. The poling conditions of the two models are the same: assuming that the holes are filled with metal electrodes [16], the poling temperature is 285 °C, the outer surface of the fiber is set to zero potential, and the potential of the two electrodes are...
uniformly 5 KV. Typical initial carrier concentrations \( c(\text{ions}) \) assumed in the simulations are: \( c(\text{Na}^+) = 1 \text{ ppm} \) uniformly distributed in the fiber at \( t = 0 \text{ s} \); \( c(\text{H}_3\text{O}^+) = \) up to 1 ppm injectable from the holes, initially zero in the entire fiber, supplied at a rate that is either constant, linearly dependent on the field at the electrode edge, or decaying exponentially as the ion supply is exhausted [8]. Ions exit the outer surface and do not return [17]. The mobility values in the simulations at 285 °C are \( 2 \times 10^{-15} \text{ m}^2/\text{Vs} \) for sodium (\( \mu_{\text{Na}^+} \)) and \( \mu_{\text{H}_3\text{O}^+}/1000 \) for \( \text{H}_3\text{O}^+ \). These values differ relatively little from those reported by An et al. [18], correcting for the temperature.

The 3D transparent schematic of the new double-hole fiber is shown in Figure 1, where the red part represents the fiber core. Geometry parameters of the new double-hole fiber (F1) and the circular double-hole fiber (F2) are shown in Table 1. The curvature of the single rounded edge in the fiber F1 is 0.087. Figure 2 shows the initial (\( t = 0 \text{ s} \)) electric potential distribution in the two models. The electric potential distribution between the electrodes of the fiber F1 is different from the electric potential distribution between the electrodes of the fiber F2 because the curvatures of the holes of the two fiber types are different. The value of the electric field (\( 1.99 \times 10^7 \text{ V/m} \)) at the core center of the fiber F1 is slightly higher than the value of the electric field (\( 1.95 \times 10^7 \text{ V/m} \)) at the core center of the fiber F2.

| Distance between center of core and center of hole 1 | 18.5 µm                      | 18.5 µm                      |
| Distance between center of core and center of hole 2 | 23.5 µm                      | 23.5 µm                      |

![Figure 2. Map of the initial (t = 0 s) electric potential across the fibers F1 (a) and F2 (b).](image)
3. Results

When the poling conditions are the same, and the circumference and the area size of the circular electrode and the rectangular electrode are almost the same, only changing the shape of electrode affects the thermal poling effect. It can be studied from the ion dynamics on the cross section of the fiber, the internal electric field at different positions of the core and the second-order nonlinearity of the core.

3.1. Ion Dynamics

The ion dynamics in the fibers F1, F2 are shown in Figure 3. In the two models, the initial concentration of Na\(^+\) uniformly distributed in the fiber is 1 ppm, and the initial concentration of H\(_3\)O\(^+\) in the fiber is 0. At 250 s, Na\(^+\) near the anodes in the fibers F1, F2 begins to migrate (dark blue indicates concentration zero). At 1000 s, Na\(^+\) in the fibers F1, F2 has migrated to the core center. However, the cation-depleted region occupies the core area in F2 is less than F1. At this time, H\(_3\)O\(^+\) is ionized from the air into the fiber and accumulates at the edge of the hole (the concentration of H\(_3\)O\(^+\) in the deep red region is highest). At 3000 s, in the fiber F1, Na\(^+\) have crossed the core center, and the negatively cation-depleted region left by Na\(^+\) migration covers the core center. H\(_3\)O\(^+\) migrates to the edge of the core under the driving of the external electric field, neutralizing the cation-depleted region near the edge of the core. However, the negatively cation-depleted region does not cover the fiber F2 core center. At 5600 s, the H\(_3\)O\(^+\) has reached the core center, and the second-order nonlinearity layer covers the fiber F1 core center. At this point, Na\(^+\) has diffused to the outer surface of the fiber. The second-order nonlinearity layer almost completely covers the fiber F2 core at 6220 s.

Figure 3. Concentration distribution of Na\(^+\) and H\(_3\)O\(^+\) in cross section of the optical fibers F1 (first two rows) and F2 (last two rows) with both electrodes biased at positive high-voltage at different poling times.
3.2. The Internal Electric Field

During the thermal poling process, the time evolution of the internal electric field for the fibers F1 and F2 are show in Figure 4. Among them, the data points of the black line, the red line, and the green line are 2 µm, 1 µm, and 0 µm from the left side of the core center respectively. In the fiber F1 core center, the internal electric field increases with time after poling of 1500 s, and reaches a maximum value of $4.8 \times 10^8$ V/m at 5420 s. However, in the fiber F2 core center, the internal electric field increases with time after the poling of 2500 s and reaches a maximum value of $4.0 \times 10^8$ V/m at 5870 s.

![Figure 4](image)

Figure 4. Time evolution of the internal electric field at the core for fibers F1 (a) and F2 (b). Different color data line comes from sampling points in different locations, 2 µm (black), 1 µm (red), and 0 µm (green) from the left side of the core center.

In the fiber F1, at 1 µm from the left side of the core center, the internal electric field reaches a maximum value of $6.2 \times 10^8$ V/m at 4700 s. At 2 µm from the left side of the core center, the internal electric field reaches a maximum value of $7.0 \times 10^8$ V/m at 4000 s. The farther from the left side of the core center, that is, the closer to the left anode, the earlier the migrated Na$^+$ and H$_3$O$^+$ reach here. Therefore, the farther away from the left side of the core center, the shorter the time corresponding to the internal electric field peak. Thus, the closer to the core center, the longer width of the second-order nonlinearity layer formed, resulting in a smaller internal electric field peak.

3.3. The Second-Order Nonlinearity

In the process of thermal poling, the internal electric field induced by thermal poling in the core center increases first and then decreases with the poling time. When the internal electric field reaches a maximum, the second-order nonlinearity layer covers the core center.

Figure 4 shows that the internal electric field in the fiber F1 (green) core center reaches a maximum about 450 s earlier than that in the fiber F2 (green) core center. And the maximum of the internal electric field induced in the fiber F1 is $0.8 \times 10^8$ V/m higher than that in the fiber F2. The induced second-order nonlinear coefficient here is measured through the $\chi_{\text{eff}}^{(2)} = 3\chi^{(3)}E_{\text{rec}}$ where the value of $\chi^{(3)}$ is assumed to be invariant and equal to $2 \times 10^{-15}$ m$^2$/Vs [19]. The maximum of the $\chi_{\text{eff}}^{(2)}$ in the center of the fiber F1 (black) is 0.05 pm/V larger than that in the center of the fiber F2 (red) is show in Figure 5.
Appl. Sci. 2019, 9, x 6 of 8

Figure 5. Time evolution of the effective second-order nonlinear coefficient at the fibers F1 (black) and F2 (red) core center.

On the entire core, the $\chi^{(2)}$ of the fiber F1 after poling of 5420 s is totally higher than that of the fiber F2 after poling of 5870 s, as shown in Figure 6a. At 5420 s, the $\chi^{(2)}$ at the center of the fiber F1 core reaches a maximum, and the 2D map of the effective second-order nonlinear coefficient distribution on the entire core at this time is shown in Figure 6b. The left half of the core is yellow, wherein the brightest color near the center of the core indicates that the effective second-order nonlinear coefficient is the highest. However, the right half of the core is blue, mainly because the second-order nonlinearity layer does not cover this part.

Figure 6. The distribution of the effective second-order nonlinear coefficient induced in the entire core of the fiber F1 after poling of 5420 s and the fiber F2 after poling of 5870 s. A 2D map of effective second-order nonlinear coefficient (b) across the fiber core is the top view of the 3D map of it (a).

In the early research on the thermal poling of double-hole optical fiber, the maximum of the $\chi^{(2)}_{\text{eff}}$ induced was 0.2 pm/V [20]. Our simulation results show that changing the structure of the holes affects the thermal poling while keeping other conditions consistent. It can be considered that under the condition of poling voltage of 5 kV and poling temperature of 285 °C, the $\chi^{(2)}_{\text{eff}}$ induced in the fiber F1 core center is about 1/5 higher than that in the fiber F2 core center. The reason for this is that the edge of the hole near the core in the fiber F1 is generally closer to the core than F2, and its single rounded edge causes ions to aggregate and have a higher concentration.

4. Conclusions

Based on the two-dimensional carrier ($\text{Na}^+$, $\text{H}_3\text{O}^+$) model, the ion diffusion and drift process of the new double-hole optical fiber and the internal electric field induced by thermal poling are analyzed by COMSOL finite element method. Compared with the circular double-hole fiber, this single rounded square electrode causes ions to aggregate and to migrate toward the core at a higher
concentration during thermal poling. Therefore, at the fiber core center, the internal electric field induced by the thermal poling of the new double-hole fiber is $0.8 \times 10^8 \text{ V/m}$ higher than that of the circular double-hole fiber, and the corresponding $\chi^{(2)}_{\text{eff}}$ increment is 0.048 pm/V. The increment of the internal electric field and second-order nonlinearity can improve the performance of electro-optic modulators and optical-to-frequency converters. The results of this paper are of great significance for the application of thermally poled fibers on nonlinear all-fiber devices and provide a new research direction for thermally poled fibers with high second-order nonlinearity.
