Abstract—Anomalously low ozone concentrations in the surface atmosphere in central Russia were recorded in spring of 2020. The increase in the ozone content usual for spring due to a seasonal increase in the temperature and light was followed by a monotonic decrease. The maximum daily values of surface ozone concentrations averaged over the month in April 2020 were three times less than the values recorded at the same time in 2019. Both a decrease in regional background ozone concentrations in the near-surface atmosphere and a decrease in the intensity of its photochemical formation were observed. The most probable cause of the observed phenomenon is a decrease in combustion product emissions into the atmosphere in China, Europe, and Russia due to the introduction of special regimes in connection with the COVID-19 pandemic.

Keywords: tropospheric ozone, atmospheric pollution, photochemical ozone formation, COVID-19 pandemic

1. INTRODUCTION

Continuous and long-term monitoring of the ozone concentration (O₃) in the near-surface atmosphere is performed in the pure (background) region of the central Russia over the past 12 years [1]. The monitoring station is arranged at the point with coordinates 56°13′ N, 51°4′ E at the Vyatskie Polyany, Kirov oblast. This place is removed from the nearest large cities for more than 100 km; there are no industrial enterprises.

The station is equipped with instrumentation for automated monitoring of ozone concentration and meteparameters. The devices are used, certificated for applications in high-accuracy monitoring and subjected to regular certification and calibration. To measure the O₃ content, a 3.02P-A chemiluminescent analyzer (OPTEK Company, Russia) is used. Analyzed atmospheric air was continuously pumped through a device measuring cell. The analyzer sensitivity was 1 μg/m³, the measurement periodicity was 1 min [2].

Ozone is formed in the surface atmosphere due to a cycle of photochemical reactions in the presence of precursor compounds, i.e., nitrogen oxides, carbon monoxide, and volatile hydrocarbons. The presence of ozone in the surface atmosphere indicates atmospheric air contamination by combustion products ejected by car and air transport, thermal power plants and other industrial sources, as well as by forest fires. Ozone in the surface atmosphere is an integral indicator of the ambient air quality. The tropospheric ozone formation rate increases with temperature and light and is maximum in the spring—summer period.

Main features of seasonal and diurnal ozone variations caused by environmental temperature and humidity variability, solar illumination intensity and duration are studied in sufficient detail.

Furthermore, the ozone content balance in the surface atmosphere is controlled by many other factors, among which are the air pollution, horizontal transfer and vertical transfer from upper layers, scavenging and dry deposition during the interaction with the ground surface, and others.

The typical annual variation of the ozone concentration in the surface atmosphere is shown in Fig. 1. Rapid and significant variations in the ozone concentration in the atmosphere, shaped as random noise in this figure, are caused by regular diurnal variations. There are easily seen a gradual increase in the ozone concentration in air in spring and high maximum levels in the summer months, reaching ~200 μg/m³.
autumn and in winter, when the solar illumination intensity decreases, the ozone concentration in the surface atmosphere decreases.

The long-term continuous monitoring of the ozone concentration in the surface atmosphere in a relatively pure (background) region allows observation of long-term trends caused by an increase in the total atmospheric pollution and climatic changes (temperature increase, an increase in the frequency of heat waves and an increase in their amplitude).

2. MONITORING RESULTS

Our close attention was directed to an analysis of the ozone content in the surface atmosphere at the beginning of 2020, when the COVID-19 pandemic began all over the world, and the activity of road and aviation transport, as well as some industrial enterprises, was limited in many countries were published [3–6]. In particular, it was fixed by satellite monitoring methods [7].

In this context, we performed a comparative analysis of the ozone concentration in the surface atmosphere in 2019 and 2020 at the Vyatskie Polyany station. Figure 2 shows the time variation of daily maximum 1-hour O₃ concentrations in January–May 2019 and 2020. We note that the observed rapid fluctuations of the data shown in Fig. 2 are caused by day to day variations of meteo parameters (temperature, illumination, humidity, and wind direction).

We can see in Fig. 2 that the ozone concentrations observed in 2020 are lower than in 2019 over the entire observation period. A noticeable deviation begins as early as the end of January. In this case, the air temperature at the beginning of 2020 was on average slightly higher than in 2019, which would cause higher O₃ concentrations. In February, the disagreement of measured values gradually increases; at the beginning of March 2020, an abrupt decrease in the ozone content in the atmosphere is observed. This time point coincides with the introduction of “high alert measures” in Russia since March 5, 2020, associated with the COVID-19 pandemic, i.e., the first limitations for the activity of road and aviation transport.

To improve the accuracy of the analysis of the observed phenomenon, we used time series processing based on the calculation of the hourly daily variations averaged over a month. In addition to a decrease in the random spread of observed data in amplitude due to averaging over a long time interval (month), this approach make it possible to retain information about diurnal dynamics and to separate contributions of
As seen in Fig. 3, the daily variations of 2019 obey the usual trend, i.e., a characteristic spring increase in the ozone concentration from month to month is observed. The maximum average values increase from ~90 μg/m³ in January to ~155 μg/m³ in May. In 2020, anomalous dynamics is observed. For January 2020, the values are ~20% less than in 2019. In February, a still larger (by ~35%) difference between maxima of 2019 and 2020 is observed, which reaches ~50% in March.
Despite the increase in the seasonal temperature, solar radiation, and daylight duration, a still larger deviation from the values of 2019 is observed. In April 2020, a maximum decrease in ozone concentrations is observed, i.e., the amplitude of the day maximum which is usually caused by air pollution by ozone precursors, becomes almost three times lower than in April 2019, and is \( \sim 60 \mu g/m^3 \). In May 2020, the observed ozone concentrations also remain significantly (more than two times) lower than those fixed in 2019.

**Figure 4.** Variations of the amplitude of acquired daily maxima \( P \) (a), morning minima \( G \) (b) and temperature (c) in January—June 2019 (closed circles) and 2020 (open circles).

Figure 4 compares the diurnally acquired maxima (Fig. 4a) and morning minima (Fig. 4b) for monthly daily variations shown in Fig. 3. These values are denoted in the April section in Fig. 3 by arrows \( P \) and \( G \), respectively. Furthermore, Fig. 4c shows the monthly averaged maximum temperature. The morning minimum \( G \) is defined by the regional background and depends on the total mass of ozone photochemically formed in the region on the eve, the intensity of scavenging and dry deposition of ozone and its transfer from neighboring regions. At constant deposition and transfer, the morning minimum will gradually decrease with decreasing air pollution leading to a decrease in the formed ozone mass. The amplitude of the daily acquired maximum is controlled by the local diurnal concentration of pollutants involved in the photochemical formation of ozone. As seen from the dynamics of daily variations, the locally acquired ozone rather rapidly decays at nightfall.

Figure 4 shows that the dynamics of the ozone content generated in the daytime differs significantly in 2019 and 2020. In 2019, this value increases correlating with the temperature increase. In 2020, such a clear dependence is not observed. From January to April 2020, this value varies rather insignificantly.
A considerable increase in the acquired maximum in 2019 and a significantly slower acquisition in 2020 at close temperature conditions indicate the integrally purer local air in 2020 in comparison with 2019.

The dynamics of morning minimum concentrations in 2019 and 2020, shown in Fig. 4b, also differs significantly. In 2019, the seasonal variation of minimum ozone concentrations, typical of winter and spring, is observed: initially, this parameter increases reaching a maximum in March, then it abruptly decreases until autumn similarly to that shown in Fig. 1 for 2015. The minimum ozone concentrations observed in spring months 2020 are two times lower than in 2019, and their monotonic decrease in time is observed. If it is considered that the ozone deposition in 2019 and 2020 differs only slightly, significantly lower morning ozone concentrations in 2020 can indicate a considerable decrease in the regional background of atmospheric air pollution in comparison with 2019. The daily smaller ozone production in the daytime leads to a gradual decrease in the background regional concentration.

The most probable cause of a decrease in both background and peak local and regional ozone concentrations in ambient air in spring 2020 can be a decrease in the atmospheric pollution, caused by a decrease in the economic activity in China, Europe, and Russia in connection with the COVID-19 pandemic. The development of the anomalous dynamics of the tropospheric ozone in central Russia coincide with the introduction of road transport restrictions and a global decrease in the economic activity in the world, resulted in a considerable decrease in combustion product emissions into the atmosphere all over the world.

3. CONCLUSIONS

In central Russia, April 2020, anomalously low ozone concentrations in the surface atmosphere were recorded. The increase in the ozone concentration, usual for spring, caused by a seasonal increase in the temperature and light was followed by a monotonic decrease. The monthly averaged maximum diurnal values observed in April 2020 were almost three times lower than those fixed at the same time in 2019.

In spring of 2020, both a decrease in regional background ozone concentrations in the surface atmosphere, and a decrease in the intensity of its photochemical formation were observed. The most probable cause of the observed phenomenon is a decrease in combustion product emissions into the atmosphere in China, Europe, and Russia due to the COVID-19 pandemic.
