Abstract: Photosynthesis by trees is expected to contribute to preventing climate change including global warming. However, the current levels of tropospheric ozone (O\textsubscript{3}) reduce the uptake of photosynthetic carbon dioxide (CO\textsubscript{2}) by forest trees in Japan, which is a concern. Furthermore, it is unknown how much O\textsubscript{3} should be reduced to prevent plants’ O\textsubscript{3}-induced damage. The objective of the present study was to assess the negative effects of the current levels of O\textsubscript{3} absorbed via stomata and the impact of its mitigation on the CO\textsubscript{2} uptake by trees in Japanese forests. Impact assessment, targeted in 2011–2015, was performed for four deciduous broad-leaved trees: Fagus crenata, Quercus serrata, Q. mongolica var. crispula, and Betula platyphylla var. japonica. The assessment was based on species-specific cumulative stomatal O\textsubscript{3} uptake (COU) and species-specific responses of annual photosynthetic CO\textsubscript{2} uptake to COU. Annual COU differed between the four trees; the average COU of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica across Japan was 41.7, 26.5, 33.0, and 29.1 mmol m\textsuperscript{-2}, respectively, and the reductions in CO\textsubscript{2} uptake by the four trees were 14.0%, 10.6%, 8.6%, and 15.4%, respectively. Further analysis revealed that reducing the atmospheric O\textsubscript{3} concentration by approximately 28%, 20%, 17%, and 49% decreased the O\textsubscript{3}-induced reductions in photosynthetic CO\textsubscript{2} uptake to 5% in F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively. In the near future, implementing mitigation measures for the O\textsubscript{3} damage in plants is expected to enhance the photosynthetic capacity of Japanese forest tree species.

1. Introduction

Climate change, including rising air temperatures and changes in precipitation, is recognized globally as a serious environmental problem [1]. Atmospheric carbon dioxide (CO\textsubscript{2}) is one of the major factors causing climate change [1]. The CO\textsubscript{2} concentration has increased to approximately 400
The increasing trend of tropospheric O\textsubscript{3} exhibits direct radiative forcing for climate change [1]. O\textsubscript{3} also has a potential for indirect radiative forcing, as it reduces the photosynthetic CO\textsubscript{2} uptake because of its high phytotoxicity [7,8]. Sitch et al. [9] suggested that indirect radiative forcing, which is the O\textsubscript{3}-induced reduction in the photosynthetic CO\textsubscript{2} fixation, could also contribute to global warming. Thus, an impact assessment of O\textsubscript{3} on photosynthetic CO\textsubscript{2} uptake is needed to support countermeasures, such as adaptation and mitigation, against the detrimental impact of O\textsubscript{3}.

Accumulated exposure over a threshold of 40 nmol mol\textsuperscript{-1} (AOT40) has been utilized to evaluate the effects of O\textsubscript{3} on tree species [10,11]. Although such an exposure-based O\textsubscript{3} index is useful for impact assessment of O\textsubscript{3} on plants because of the ease in calculation and fewer required parameters, stomatal O\textsubscript{3} uptake is more related to leaf O\textsubscript{3} damage than the exposure-based O\textsubscript{3} index [7,12]. In Europe, the impact of O\textsubscript{3} on trees has been assessed based on cumulative stomatal O\textsubscript{3} uptake (COU) [13]. However, the impact assessment on trees based on stomatal O\textsubscript{3} uptake is extremely limited in Asia. The tropospheric O\textsubscript{3} concentration in Asia is relatively high in the world [14], indicating remarkable damage of O\textsubscript{3} on plants grown in Asia. Therefore, it is necessary to assess the impact of O\textsubscript{3} on the photosynthetic CO\textsubscript{2} uptake of forest tree species in Asia.

In Japan, the tropospheric O\textsubscript{3} concentration has been increasing although the concentration of its precursors, such as nitrogen oxides (NO\textsubscript{x}) and volatile organic compounds (VOCs), has decreased [15]. The increasing trend of O\textsubscript{3} concentration is mainly caused by the reduction in the titration effect of nitric oxide (NO) and partly increasing transboundary transportation of O\textsubscript{3} and/or its precursors from the Asian continent [15]. Current levels of O\textsubscript{3} are related to growth inhibition of plants and forest decline in Japan [16,17]. Thus, countermeasures may need to be implemented against O\textsubscript{3} damage to plants. Mitigation, which refers to the reduction of the atmospheric O\textsubscript{3} concentration here, is a fundamental and effective countermeasure against the damage of O\textsubscript{3} to plants. To date, however, limited information is available on the effects of the mitigation of O\textsubscript{3} on plants and on how much surface O\textsubscript{3} concentration should be reduced.

Recently, Yamaguchi et al. [18] evaluated the species-specific responses of cumulative photosynthetic CO\textsubscript{2} uptake to COU of the leaves in four Japanese forest tree species: F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica. Using these species-specific responses, we aimed (1) to evaluate the effects of the current levels of O\textsubscript{3} absorbed into the leaves via stomata on the photosynthetic CO\textsubscript{2} uptake by the four representative Japanese deciduous broad-leaved tree species and (2) to assess the impact of the mitigation of O\textsubscript{3}, i.e., reducing surface O\textsubscript{3} concentration, on the CO\textsubscript{2} uptake by the tree species.

2. Materials and Methods

2.1. Overview of Procedure for Simulating Impact and Mitigation Effects of O\textsubscript{3} on Photosynthetic CO\textsubscript{2} Uptake

In the present study, the impact and mitigation effects of O\textsubscript{3} on the annual photosynthetic CO\textsubscript{2} uptake per area of sunlit first-flush or early leaves of four Japanese deciduous broad-leaved trees—Fagus crenata, Quercus serrata, Quercus mongolica var. crispula, and Betula platyphylla var. japonica—were simulated in 2011–2015. First, environmental data and phenological data, such as leaf emergence date and leaf senescence date, for estimating stomatal O\textsubscript{3} uptake were collected from the databases of Japan Meteorological Agency (https://www.data.jma.go.jp/obd/stats/etrn/index.php), National Institute for Environmental Studies (https://www.nies.go.jp/igreen), and Moderate Resolution Imaging Spectroradiometer (MODIS) product (https://doi.org/10.5067/MODIS/MCD12Q2.006). Second, COU at the O\textsubscript{3} monitoring stations was estimated for the four tree species using species-specific parameters of the stomatal O\textsubscript{3} uptake model developed by Kinose et al. [19]. The meteorological and phenological data to calculate the COU were obtained from nearby meteorological stations and nearby areas where
the trees were distributed, respectively. Third, COU in the tree distribution areas (Ministry of the Environment, http://www.biodic.go.jp/index.html) was estimated by interpolating the COU at the monitoring stations of O$_3$ using ordinary kriging. Fourth, according to species-specific responses of annual CO$_2$ uptake to COU reported by Yamaguchi et al. [18], O$_3$-induced reductions in CO$_2$ uptake for the four trees were calculated. Finally, the effects of O$_3$ mitigation, i.e., impact of reducing the surface O$_3$ concentration, on CO$_2$ uptake were calculated for the four tree species by simulating the input O$_3$ concentrations. A summary of information on simulation settings, required data, and data sources is provided in Table 1.

Table 1. Simulation setting and data sources for the impact assessment of O$_3$ on annual CO$_2$ uptake.

| Parameter | Value or Source |
|-----------|----------------|
| Targeted year | 2011–2015 |
| Targeted leaves | Sunlit leaves |
| Calculation time step | 1 h |
| Latitude | From 24° to 46° |
| Longitude | From 122° to 154° |
| Meteorological factors | Japan Meteorological Agency (https://www.data.jma.go.jp/obd/stats/etrn/index.php) |
| Ozone concentration | National Institute for Environmental Studies (https://www.nies.go.jp/igreen/) |
| Tree distribution (45′′ × 30′′ mesh) | Ministry of the Environment (http://www.biodic.go.jp/index.html) |
| Parameters of stomatal conductance model | Kinose et al. [19] |
| Phenology (leaf emergence date, leaf senescence date, and $f_{phen}$) | Friedl et al. [20] (https://doi.org/10.5067/MODIS/MCD12Q2.006) |
| Response of annual photosynthetic CO$_2$ uptake to COU | Yamaguchi et al. [18] |

2.2. Simulating Cumulative Stomatal O$_3$ Uptake

COU is given by

$$\text{COU} = \Sigma F_{st}$$  \hspace{1cm} (1)

$$F_{st} = [O_3]/(R_{s,O3} + R_{b,O3})$$  \hspace{1cm} (2)

$$R_{s,O3} = 1/(0.663 \times g_s)$$  \hspace{1cm} (3)

$$R_{b,O3} = 1.3 \times 150 \times (L_d/u)^{0.5}$$  \hspace{1cm} (4)

where $F_{st}$ is the stomatal O$_3$ uptake, [O$_3$] is the atmospheric O$_3$ concentration, $R_{s,O3}$ and $R_{b,O3}$ are the stomatal resistance and leaf boundary layer resistance to O$_3$, respectively, $g_s$ is the stomatal conductance to H$_2$O, $L_d$ is the crosswind leaf dimension, and $u$ is the wind speed.

The $g_s$ was estimated according to the $g_s$ model provided by Kinose et al. [19], originally developed by Jarvis [21]:

$$g_s = g_{max} \times f_{phen} \times f_{light} \times \max(f_{min}, f_{temp} \times f_{VPD} \times f_{SWC} \times f_{O3conc})$$  \hspace{1cm} (5)

where $g_{max}$ is the maximum $g_s$, $f_{min}$ is the ratio of minimum $g_s$ to $g_{max}$, and $f_{phen}, f_{light}, f_{temp}, f_{VPD}, f_{SWC}$, and $f_{O3conc}$ represent responses of $g_s/g_{max}$ to leaf phenology, photosynthetic photon flux density (PPFD), air temperature, vapor pressure deficit, volumetric soil water content, and atmospheric O$_3$ concentration, respectively. These parameters are species-specific and were essentially based on our previous results (see details in Kinose et al. [19]). The leaf emergence date and leaf senescence date
were provided by MODIS Land Cover Dynamics Product, MCD12Q2 v. 006, in 500-m grids in the world. Seasonal changes in enhanced vegetation index (EVI) of the MCD12Q2 were substituted for the $f_{\text{phen}}$. These phenological data were obtained considering tree distribution using vegetation raster data (45” × 30” mesh) of the National Survey on the Natural Environment (Ministry of the Environment), indicating the distribution of dominant species, although uncertainties exist in the dataset because the forest is not necessarily pure. In the present study, $g_s$ was considered to be unchanged according to soil water content, i.e., $f_{\text{SWC}} = 1$, because the amount of precipitation was relatively high in Japan (annual mean precipitation: approximately 1700 mm).

The concentrations of photochemical oxidants are officially monitored at approximately 1200 monitoring stations across Japan (National Institute for Environmental Studies). In the present study, the concentration of photochemical oxidants was considered as the concentration of O$_3$ [10]. The meteorological data such as air temperature and wind velocity officially monitored at approximately 1300 monitoring stations throughout Japan (Japan Meteorological Agency) were used for the calculation of COU. PPFD was estimated based on the study by Masaki et al. [22]. The vapor pressure deficit (VPD) was estimated regarding the vapor pressure during the daytime as the saturated vapor pressure at the minimum temperature on the day, as the relative air humidity is almost 100% at the minimum temperature. The distribution of monitoring stations of photochemical oxidants and meteorological factors and regional partition in Japan is shown in Figure 1.

![Figure 1](image_url)

**Figure 1.** Distribution of monitoring stations of photochemical oxidants (red circle) and meteorological factors (green circle) and regional division in Japan.

The gaussian model was used as a semi-variogram model in the ordinary kriging to interpolate the annual COU at the O$_3$ monitoring stations, which was clipped by the tree distribution. As in a previous study [23], we did not interpolate the input data for calculating COU, i.e., meteorological data and O$_3$ data, because the interpolation is extremely difficult due to enormous calculation time. Kriging interpolation was performed using SAGA GIS v. 6.4.0 [24].
2.3. Impact Assessment of O₃-induced Reduction in Annual Photosynthetic CO₂ Uptake

The responses of annual photosynthetic CO₂ uptake to COU were fitted by the Weibull function, and the O₃-induced reduction in annual CO₂ uptake was calculated as follows:

\[
\text{O₃-induced reduction in annual photosynthetic CO}_2 \text{ uptake} = 100 - 100 \times \exp[-(\text{COU}/\omega)^\lambda]
\]

where \(\omega\) and \(\lambda\) are species-specific parameters of the Weibull function. \(\omega\) and \(\lambda\) were originally proposed by Yamaguchi et al. [18] and were modified to make the intercept 100 (Figure 2).

![Figure 2. Responses of annual CO₂ uptake per unit leaf area to cumulative stomatal O₃ uptake (COU) of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica seedlings. These responses were obtained from the study by Yamaguchi et al. [18] with slight modifications. The Y-intercept was modified to 100 in the present study. Plots indicate the first-flush or early leaves (○) or second-flush or late leaves (×). The Weibull function was fitted to the response, and its parameters, \(\omega\) and \(\lambda\), and the mean absolute error (MAE, %) are indicated in each figure.](image)

Since previous studies indicated that leaf morphological and physiological characteristics, such as leaf mass per area and gross photosynthetic rate, are related to the sensitivity to O₃ [7,25], the leaf-level photosynthetic sensitivity to O₃ might be different between seedlings and mature trees due to the differences in their leaf characteristics. However, this has not been clarified to date. In the present study, therefore, we assumed that the responses of CO₂ uptake to COU obtained in the seedlings in Yamaguchi et al. [18] were the same as those in the mature trees, although this might cause estimation errors in the impact of O₃ on CO₂ uptake to some extent.

3. Results

Figure 3 shows the spatial distribution of 5-year mean annual COU per unit leaf area of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica in Japan in 2011–2015. The annual COU in each year is indicated in Figure 4. The 5-year mean COU averaged across Japan differed
between the tree species, being 41.7 (2011–2015 range: 37.2–46.2), 26.5 (24.1–27.9), 33.0 (29.7–34.9), and 29.1 (27.8–30.6) mmol m$^{-2}$ in the leaves of *F. crenata*, *Q. serrata*, *Q. mongolica* var. *crispula*, and *B. platyphylla* var. *japonica*, respectively. COU was relatively low in the Tohoku and Hokkaido regions, and relatively high in Kanto, Chubu, Kinki, and Chugoku regions relative to the other regions.

**Figure 3.** Spatial distribution of 5-year mean annual cumulative stomatal O$_3$ uptake (COU) per unit leaf area (mmol m$^{-2}$) of *F. crenata*, *Q. serrata*, *Q. mongolica* var. *crispula*, and *B. platyphylla* var. *japonica* in 2011–2015.
The 5-year mean O$_3$ concentration to the O$_3$-induced reduction in annual CO$_2$ uptake averaged across Japan differed between the tree species, being 14.0% (2011–2015 range: 9.5–18.7%), 10.6% (7.3–12.1%), 8.6% (6.2–10.0%), and 15.4% (14.2–16.7%) in the leaves of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively.

Figure 5 shows the spatial distribution of the 5-year mean O$_3$-induced reduction in annual CO$_2$ uptake per unit leaf area of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica in Japan in 2011–2015. The O$_3$-induced reduction in annual CO$_2$ uptake each year is shown in Figure 6. The 5-year mean O$_3$-induced reduction in CO$_2$ uptake averaged across Japan differed between the tree species, being 14.0% (2011–2015 range: 9.5–18.7%), 10.6% (7.3–12.1%), 8.6% (6.2–10.0%), and 15.4% (14.2–16.7%) in the leaves of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively.

Figure 7 demonstrates the impact of O$_3$ mitigation on the annual CO$_2$ uptake per unit leaf area of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica in 2011–2015. A curvilinear response of the reduction in the surface O$_3$ concentration to the O$_3$-induced reduction in the annual CO$_2$ uptake was observed in the four tree species. To diminish the O$_3$-induced reduction in the annual CO$_2$ uptake to a value of 5%, the surface O$_3$ concentrations should be reduced by 28% (2011–2015 range: 19–34%), 20% (11–23%), 17% (8–21%), and 49% (46–51%) for F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively.
Figure 5. Spatial distribution of 5-year mean O₃-induced reduction in annual CO₂ uptake per unit leaf area (%) of *F. crenata*, *Q. serrata*, *Q. mongolica* var. *crispula*, and *B. platyphylla* var. *japonica* in 2011–2015.
Figure 6. Ozone-induced reduction in annual CO$_2$ uptake per unit leaf area (%) of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica in 2011–2015. Horizontal solid lines show the median, boxes show the first through third interquartile ranges, and whiskers show the minimum and maximum reductions in CO$_2$ uptake.

Figure 7. Effects of O$_3$ mitigation for the O$_3$-induced reduction in annual CO$_2$ uptake per unit leaf area (%) of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica in Japan in 2011–2015. The range of the O$_3$-induced reduction in annual CO$_2$ uptake in 2011–2015 is represented in gray, and the means are indicated by the solid black lines.

4. Discussion

The present study firstly evaluated the impact of the current levels of O$_3$ absorbed via stomata on the annual cumulative photosynthetic CO$_2$ uptake per unit leaf area of four Japanese forest tree...
species. The O\(_3\)-induced reduction in annual CO\(_2\) uptake averaged across Japan was 14.0%, 10.6%, 8.6%, and 15.4% in F. crenata, Q. serrata, Q. mongolica var. crisulpa, and B. platyphylla var. japonica, respectively (Figures 5 and 6). This result indicated that the current atmospheric O\(_3\) concentrations have the potential to reduce the capacity of CO\(_2\) uptake by Japanese forest tree species.

Kinose et al. [19] indicated that when the four tree species were grown in the same environmental conditions, the COU was ranked as follows: B. platyphylla var. japonica > F. crenata > Q. mongolica var. crisulpa > Q. serrata. However, the tree distributions and environmental growth conditions greatly differ between the four tree species. Betula platyphylla var. japonica is mainly distributed in the Hokkaido region, where the stomatal O\(_3\) uptake was relatively low (Figure 3). As a result, the COU of B. platyphylla var. japonica averaged across Japan was lower than that of F. crenata and Q. mongolica var. crisulpa (Figures 3 and 4). Nevertheless, the impact of O\(_3\) on the COU of B. platyphylla var. japonica was more remarkable than that of the other tree species (Figures 5 and 6). This is due to the relatively higher sensitivity of photosynthetic CO\(_2\) uptake to COU in B. platyphylla var. japonica (Figure 2).

Several studies have assessed the effects of O\(_3\) absorbed via stomata on gross or net primary production (GPP or NPP, respectively) in forest ecosystems [9,26]. Lombardozzi et al. [26] estimated the O\(_3\)-induced reduction in GPP targeted at global forest based on the relationships between COU and stomatal conductance derived in a specific tree species, the tulip poplar. Sitch et al. [9] evaluated the impact of O\(_3\) on the GPP of five plant functional types, namely broad-leaved trees, conifers, C\(_3\) grasses, C\(_4\) grasses, and shrubs, considering different sensitivities of the net photosynthetic rate to O\(_3\) among the plant functional types. However, the sensitivity of the photosynthetic capacity to O\(_3\) is extremely different between tree species possibly because of the differences in the defensive ability to O\(_3\) [18]. The advantage of our impact assessment is that we considered the species-specific responses of photosynthetic CO\(_2\) uptake to COU, even though there was uncertainty in the evaluation of O\(_3\)-induced reduction rates by 3.1%, 3.6%, 3.8%, and 6.2% in F. crenata, Q. serrata, Q. mongolica var. crisulpa, and B. platyphylla var. japonica, respectively (Figure 2).

In the present study, COU and O\(_3\)-induced reduction rates of CO\(_2\) uptake were relatively high in Kanto, Chubu, Kinki, and Chugoku regions (Figures 3–6). Akimoto et al. [15] reported that the contribution of the transboundary transport of O\(_3\) from the Asian continent to its concentration in Japan seemed to be relatively small except for that in the Kyushu region. According to Nagashima et al. [27], the contribution to the O\(_3\) concentrations in Japan from China and the Korean Peninsula were estimated to be approximately 10% and 4%, respectively, although the domestic contribution was approximately 42% in the Japanese summer. Furthermore, O\(_3\) is recognized as a short-lived climate pollutant (SLCP). These results indicate the necessity and effectiveness of domestic countermeasures against O\(_3\) formulation for avoiding the O\(_3\)-induced reduction in CO\(_2\) uptake by Japanese forest tree species.

The concept of critical level of O\(_3\) has been discussed in Europe to prevent its damage to plants. The critical levels of O\(_3\) for European beech and European birch were defined as 5 ppm h of daylight AOT40 to diminish the growth reduction to a value of 5% [28]. In Japan, a provisional critical level based on AOT40 is suggested for the tree species sensitive to O\(_3\), namely 8–15 ppm h (6 months) corresponding to a 10% growth reduction [29]. However, the critical level based on stomatal O\(_3\) uptake has been developed because the O\(_3\) absorbed through stomata is more physiologically related to the O\(_3\) damage to tree growth [30]. Critical levels of the two European trees were set at 5.2 mmol m\(^{-2}\) of POD\(_1\) (phytotoxic O\(_3\) dose above the threshold of 1 mmol m\(^{-2}\) s\(^{-1}\)) corresponding to a 4% growth reduction [28]. Although this concept of the critical level of O\(_3\) is more scientifically plausible, how much O\(_3\) should be reduced is unclear. While the stomatal O\(_3\) uptake concept is significantly useful to assess the impact of O\(_3\) on plants, to create and implement mitigation measures against O\(_3\) damage to plants, determining the atmospheric O\(_3\) concentration is needed. To the best of our knowledge, the present study is the first to evaluate the impact of the mitigation of O\(_3\) absorbed via stomata on the annual photosynthetic CO\(_2\) uptake. As a result, we clarified that O\(_3\) concentrations should be reduced by 28% (2011–2015 range: 19–34%), 20% (11–23%), 17% (8–21%), and 49% (46–51%) for F.
crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively, to diminish the O3-induced reduction to a value of 5% (Figure 7). Because the domestic contribution of O3 formation is 42% in the Japanese summer [27], it would be impossible to prevent the O3 damage by 5% for B. platyphylla var. japonica by domestic control of the emission of O3 precursors. In contrast, such a mitigation measure may be effective for the other tree species: F. crenata, Q. serrata, and Q. mongolica var. crispula. We provisionally propose that the O3 concentration should be reduced by approximately 30% to decrease its damage on CO2 uptake below 5% in some Japanese forest tree species. We hope our results will contribute to creating and implementing mitigation measures against the detrimental impact of O3 on forest tree species in Japan and to enhancing their photosynthetic CO2 uptake.

There are some uncertainties and future issues in the assessment on the impact of O3 on the photosynthetic CO2 uptake by forest tree species, including estimation accuracies of the stomatal conductance and errors of COU induced by the interpolation or extrapolation by kriging. One of the major issues is whether the parameterization results of the stomatal conductance model and the responses of CO2 uptake to COU obtained in the particular environment of the experimental studies by Kinose et al. [19] and Yamaguchi et al. [18] could be applicable to the whole Japan in 2011–2015. Alonso et al. [31] reported different parameter values of the stomatal conductance model of Quercus ilex between marine-influenced sites and continental sites, indicating that the values of the model parameters depend on the environmental growth conditions of the trees. Actually, the optimum air temperature for stomatal opening depends on the growth conditions of F. crenata seedlings in Japan possibly because of an acclimation to the air temperature [32]. Therefore, the application of the stomatal conductance model of Kinose et al. [19] to the whole Japan may cause estimation errors of COU. Furthermore, Kinose et al. [7] indicated a higher sensitivity in the high-fertilized F. crenata seedlings due to the higher COU. In a forest area with a higher soil nutrient status, stomatal conductance may be higher via photosynthetic enhancement and be limited to some extent with shorter leaf longevity [33], indicating nutrient-dependent $g_{\text{max}}$ and $f_{\text{phen}}$. In the present study, nutrient-dependent $f_{\text{phen}}$ may be partly considered because $f_{\text{phen}}$ was determined from the seasonal changes in EVI provided by satellite data. However, $g_{\text{max}}$ was regarded as a constant in the present study, which could cause estimation errors of COU. The nutrient-induced modification of $g_{\text{max}}$ in the calculation of COU is an issue to be considered in the future. On the other hand, the responses of CO2 uptake to COU can differ depending on the growth conditions because the environmental conditions, such as atmospheric CO2 concentration and soil drought, affect the leaf detoxification capacity to O3 [34,35]. However, information on the effects of tree growth environment on the responses of CO2 uptake to COU is insufficient to date. In order to perform a more accurate evaluation of the impact of O3 on the photosynthetic CO2 uptake by forest tree species, the effects of environmental growth conditions on COU and responses of CO2 uptake to COU should be considered.

5. Conclusions

We evaluated the O3-induced reduction in annual CO2 uptake per unit leaf area of Fagus crenata, Quercus serrata, Quercus mongolica var. crispula, and Betula platyphylla var. japonica in 2011–2015 based on the COU per unit leaf area and species-specific responses of the annual CO2 uptake to COU. The current levels of ambient O3 reduced the annual CO2 uptake of F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica by 14.0%, 10.6%, 8.6%, and 15.4%, respectively. Further analysis revealed that, to diminish the O3 damage to a value of 5%, O3 concentrations should be reduced by 28%, 20%, 17%, and 49% for F. crenata, Q. serrata, Q. mongolica var. crispula, and B. platyphylla var. japonica, respectively. We hope that implementing mitigation measures against O3 damage will help increase the photosynthetic CO2 uptake by Japanese forest tree species.

Acknowledgments: The authors would like to thank Prof. Takayoshi Koike (Hokkaido University) and Dr. Mitsutoshi Kitao (Forestry and Forest Products Research Institute) for their valuable suggestions and technical support. The authors are greatly indebted to Dr. Makoto Watanabe (Tokyo University of Agriculture and Technology) for his technical support.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript; or in the decision to publish the results.
