Abstract
Ocean acidification substantially alters ocean carbon chemistry and hence pH but the effects on sea ice formation and the CO₂ concentration in the enclosed brine channels are unknown. Microbial communities inhabiting sea ice ecosystems currently contribute 10–50% of the annual primary production of polar seas, supporting overwintering zooplankton species, especially Antarctic krill, and seeding spring phytoplankton blooms. Ocean acidification is occurring in all surface waters but the strongest effects will be experienced in polar ecosystems with significant effects on all trophic levels. Brine algae collected from McMurdo Sound (Antarctica) sea ice was incubated in situ under various carbonate chemistry conditions. The carbon chemistry was manipulated with acid, bicarbonate and bases to produce a pCO₂ and pH range from 238 to 6066 μatm and 7.19 to 8.66, respectively. Elevated pCO₂ positively affected the growth rate of the brine algal community, dominated by the unique ice dinoflagellate, Polarella glacialis. Growth rates were significantly reduced when pH dropped below 7.6. However, when the pH was held constant and the pCO₂ increased, growth rates of the brine algae increased by more than 20% and showed no decline at pCO₂ values more than five times current ambient levels. We suggest that projected increases in seawater pCO₂, associated with OA, will not adversely impact brine algal communities.

Introduction
Ocean acidification (OA) is a direct ocean response to anthropogenic CO₂ emissions and will continue irrespective of whether the planet warms. The increase in atmospheric CO₂ levels from the present (~400 μatm) to levels likely by the end of the century (~700 μatm, [1]), will lead to an increase in average seawater CO₂ concentration from around 12.5 μmol kg⁻¹ to ~20 μmol kg⁻¹. This will be accompanied by a fall in pH from a global preindustrial average of ~8.2 to 7.8. Current pH values adjacent to Antarctica are 8.019–8.045 [2]. Some microalgal species will benefit from increased CO₂ concentrations, which will facilitate faster rates of photosynthesis and growth. Although many species, including most diatoms, possess effective carbon-concentrating mechanisms (CCM), they may still benefit from decreased costs for carbon acquisition [3,4,5]. Whether global marine primary production will benefit from projected changes in CO₂ levels will largely be determined by nutrient supply and grazer impact since most oceans are oligotrophic and limited by nutrients and/or light rather than CO₂ availability [6,7,8,9].

The direct effect of oceanic pH on microalgal cells is less clear but recent work has demonstrated that it can modify intracellular pH and affect membrane potential, energy partitioning and enzyme activity [10,11]. Many coastal and estuarine phytoplankton are unaffected by external pH changes in the range 7.8–8.5, probably because this range reflects natural diurnal and seasonal changes in many coastal environments [12,13,14]. Natural increases in pH to >10 have been reported from dense phytoplankton blooms before limiting access to CO₂ causes photosynthesis to be impaired. Furthermore, microalgae living in extreme environments are able to tolerate short term exposure over a very large range in pH (3–11) [15] but in the ocean it is likely to be the resultant changes in nutrient availability and not pH itself, which will have the greatest impacts on growth and survival [6].

The situation in sea ice ecosystems, however, is quite different to that in the open sea. During ice formation, internal gas concentrations are heavily modified by exclusion of gases from the ice crystal structure. This results in a steep decline in pH, changes to gas solubility at high salinity and low temperature often resulting in supersaturation and outgassing [16]. Internal liquid seawater temperatures can drop to below −15°C with salinities fluctuating between 173 in winter and 0 in summer [16]. Photosynthetic activity has been recorded at temperatures below −10°C [17]. However, in spring and summer this trend is usually overridden by the photosynthetic activity of dense microalgal communities that cause the pH to rise as a result of the depletion of the dissolved CO₂. Values of up to 8.9, for instance, have been reported from platelet ice [18] and up to 9.9 in brine channels within the ice matrix [16].

Sea ice microbial communities are a critical component of polar marine ecosystems, contributing 10–50% of the annual primary production of polar seas [19], supporting overwintering zooplankton species, especially Antarctic krill, and seeding spring phytoplankton blooms. Ocean acidification will be experienced most
CO$_2$, pH, Sea Ice Algae, Brine, Antarctica

strongly in these ecosystems and is likely to have significant effects on all trophic levels [20]. These communities are a close association between microalgae, heterotrophic bacteria and heterotrophic protists. Algae and other microorganisms proliferate in sea-ice during spring with bacterial production coupled tightly to algal production [21]. In some communities, such as those at the surface of the ice or those in brine channels, cells grow despite exposure to extremes of temperature and salinity, while those on the underside of the ice remain at close to freezing point. Brine channel and surface communities have only limited access to the underlying water column and consequently their CO$_2$ (and nutrient) supply becomes severely restricted. Under these circumstances, restricted CO$_2$ supply limits microalgal growth [22]. Thus, unlike planktonic ecosystems where CO$_2$ is rarely in short supply, in sea ice brine systems the shortage is often acute and the addition of CO$_2$ as a result of OA may partially alleviate this stress. Nitrate also becomes less significant as ammonium levels increase at lower pH with enhanced disassociation to ammonia, which is more readily assimilated [18]. In addition, elevated oxygen levels may negatively influence growth [23] as do processes associated with iron and nitrogen transformation [10]. By comparison, algal communities on the underside of the ice usually experience replete nutrient conditions and an unrestricted CO$_2$ supply. Sea ice microbial communities are already living at physiochemical extremes and additional changes such as a decrease in pH have the potential to shift environmental conditions beyond physiologically tolerable levels.

At its most fundamental level, ocean acidification is about the effects of changing resource availability (i.e. nutrients and CO$_2$) coupled with cellular energy demands and environmental changes in pH. Here we report the in situ response of ice algal communities to changing carbonate speciation. This study is the first in situ study of the response of sea ice brine algae to manipulated carbon chemistry.

Materials and Methods

The sea ice incubation experiments were conducted on 16-26 Nov, 2012 at Cape Evans, McMurdo Sound (77° 38’S, 166°24’E), Antarctica. Brine was collected from 0.5 m deep sack holes, drilled with a 20 cm diameter motorised auger at the beginning of each experiment [Jiffo, USA]. The temperature and salinity of the brine was measured prior to chemical manipulation and preparation of each experiment, using a digital thermometer (Digitron, 2098T) and a refractometer (HANNA Instruments Inc. Woonsocket-RI-USA, Model: HI96822). After chemical manipulation (see below), five replicates were decanted into clear 250 ml polycarbonate vials with clear lids leaving no headspace. The vials containing the brine algae were placed in 13 cm diameter holes that had been cored to a depth of 0.5 m with a motorised ice corer (Kovacs, USA). The ice cores initially extracted from each hole was subsequently placed on top of the vials, generating a natural light and temperature environment. Irradiance was measured with a Biospheraerical QSP 200 4t light meter.

The work program and sampling protocol for these experiments were approved under the provisions of the Antarctic Treaty by a permit (issued to Ken Ryan) by Antarctica New Zealand. No protected or endangered species were used in the experiments and no specially protected areas were visited. All experiments were conducted in situ, in Antarctica.

CO$_2$ Manipulation

The, brine carbonate chemistry was manipulated by the addition of HCl, NaOH and NaHCO$_3$. In the first experiment (5 treatments and 5 replicates), total alkalinity (TA) was manipulated while keeping the DIC concentration constant by the addition of HCl or NaOH resulting in a pH (total scale) and pCO$_2$ gradient from 7.19 to 8.66 and from 178 to 5095 μatm, respectively. In the second experiment (4 treatments and 5 replicates), the carbonate system was manipulated by addition of NaHCO$_3$ and NaOH keeping the pH constant (8.02±0.05) while applying a pCO$_2$ gradient ranging from 505 to 2477 μatm.

Samples for dissolved inorganic carbon (DIC) and TA were taken from the bulk samples at the beginning of each experiment and then from the replicates at the end. Samples were taken for DIC, TA, chl-a, Coulter Multisizer-analysis and PAM fluorometry at the beginning and end of each experiment. DIC samples were filtered through a sterile filter (pore size 0.2 μm) into 12.5 ml Labco Exetainers® avoiding air contact, poisoned with HgCl$_2$ and sealed air tight. TA samples were filtered through GF/F filters (used for chl-a analysis), poisoned with HgCl$_2$ and stored in 250 ml polyethylene flasks. Samples for Coulter-Multisizer analysis (12 ml) were fixed with Lugol’s solution and stored in the dark until analysed.

The carbonate system was calculated from temperature, salinity, TA and DIC measurements using the program CO2sys (version 1.05 by E Lewis and DWR Wallace) with dissociation constants for carbonic acid [24]. DIC and TA samples were analysed as the mean of triplicate measurements with the infrared detection method using an Apollo SciTech DIC-Analyzer (Model AS-C3) and the potentiometric titration method with modification for high alkalinity [25,26] respectively. Data were corrected to Certified Reference Materials (CRM) (Scripps Institution of Oceanography, USA). Consecutive measurements of the Dickson standard resulted in an average precision of >99.9% for both TA and DIC analysis.

Coulter Multisizer Analysis

Samples were analysed as the mean of triplicate measurements with a Beckman Coulter Multisizer IV equipped with a 100 μm aperture covering particle volume range from 4 to 113,097 μm$^3$.

Chlorophyll Analysis and Fluorometry

Samples were filtered onto 42 mm diameter Whatman GF/F filters. The filters were then extracted in 10 ml of 90% methanol for 12 hours at 4°C in the dark. Chlorophyll-a was measured on a Turner 10AU fluorometer using the acidification method [27].

A WaterPAM (Walz GmbH, Germany) was used for the maximum quantum yield ($F_v/F_m$) measurements. Gain settings were between 18 and 22. All samples were dark adapted at −2°C for one hour prior to measurement. One-way ANOVA was used to compare end-point data for the control and treatment.

Data Analysis

One-way analysis of variance (ANOVA) and Tukey post hoc tests were used to test for significant differences within/among treatments using SPSS v20 (IBM). If heteroscedastic, the data was transformed prior to analysis.

Results

The sea ice at Cape Evans, McMurdo Sound, in November-December 2012 was 1.7 m thick with no snow cover. The brine community was strongly dominated by the dinoflagellate, Polarella

PLOS ONE | www.plosone.org 2 January 2014 | Volume 9 | Issue 1 | e86984
glacialis. Maximum midday irradiances were approximately 100–120 μmol photons m⁻² s⁻¹ in the 50 cm deep holes.

Reduced pH and Increased CO₂ Experiment
Initial brine salinity was 65 and the temperature was −3°C. Initial pH and pCO₂ were 7.84 and 1288 μatm respectively. Manipulated pH and pCO₂ were between 8.53 to 7.11 and 238 μatm to 6066 μatm respectively (Table 1). Initial chl-a concentration in the brine was 0.553±0.058 μg chl-a l⁻¹ and the initial biovolume of microalgae was 1.36×10⁵ μm³/ml. Growth rate estimates from biovolume were consistently higher than estimates from chlorophyll measurements but indicated a similar trend with highest growth rates at pH = 8.37 and lowest at pH = 7.19 (Figure 1a). Initial Fv/Fm was 0.32±0.02. At the end of the incubation values ranged from 0.30±0.15 at pH 7.19 to 0.57±0.09 at pH = 8.66 (Figure 2a) but these differences were not significantly different (p>0.05).

Constant pH (8.02) and Increased CO₂ Experiment
Initial brine salinity was 54 and brine temperature was −2.5°C. Initial pH and pCO₂ were 8.02 and 587 μatm respectively. Manipulated pH remained constant at approximately 8.0, manipulated pCO₂ varied between 587 and 2464 μatm (Table 1). Initial chl-a concentration was 5.031 μg chl-a l⁻¹ and the initial microalgal biovolume was 4.97×10⁶ μm³/ml. Estimated growth rates from chlorophyll and biovolume measurements increased with pCO₂ (Figure 1b). Fv/Fm exhibited no significant difference with respect to CO₂ concentration (p>0.05, Figure 2b).

Discussion
OA produces both a drop in pH (and calcium carbonate saturation state) and a rise in CO₂ concentration and these changes produce quite different results. While a decline in calcium carbonate saturation state primarily impacts calcifiers, an increase in CO₂ availability potentially impacts photosynthesis in all autotrophs [20,28]. Bach et al. [28] attempted to isolate the effects of reduced pH and elevated pCO₂ on the calcifier, Emilia huxleyi. They found that growth rates were directly related to CO₂ at low pCO₂ but at higher CO₂ levels they were adversely affected by associated decreases in pH. In the experiments described here, the carbonate chemistry was similarly manipulated to identify and then isolate the differing effects of reduced pH and elevated CO₂ on sea ice brine communities.

The brine algal community was incubated under two different sets of conditions. In the first experiment the alkalinity remained constant and the pCO₂ was manipulated without controlling the pH. This facilitated pH levels that ranged between 8.66 and 7.19 and pCO₂ that ranged between 178 and 5095 μatm. Under these conditions growth was maximal at a pH of 8.39 (346 μatm). When the pH was held constant at ~8.02 and the pCO₂ manipulated, growth and Fv/Fm continued to increase from pCO₂ of 505 μatm to 1780 μatm and then remained approximately constant up to 2477 μatm, i.e. growth reached a maximum at four times present atmospheric CO₂ concentration and remained maximal to at least six times. The results presented here are consistent with those of Bach et al. [29], showing no change in growth rate with increasing CO₂ at low concentrations but were adversely affected by decreasing pH (<~7.2) at higher concentrations. These experiments showed that greater falls in pH to approximately 7.2 reduced the growth rate by almost 50%. However, if the pH remained at ~8.0, increased CO₂ resulted in a growth rate increase of approximately 20%.

Responses of microalgal taxa in OA experiments have been quite variable. Several recent studies have found that at elevated CO₂ concentrations (up to 1000 μatm) photosynthesis and growth tends to increase at low irradiances but decrease at higher irradiances [30,31,32,33]. In particular, it has been found that elevated CO₂ levels cause an onset of photoinhibition at lower irradiances [32]. This response, however, is not universal. While

many studies report that diatom growth rates respond positively to moderate increases in pCO2 [33,34,35], others showed little or no change [36,37,38,39]. With dinoflagellates also, many have shown little response to changes in pCO2 that are consistent with end of century scenarios [40]. Some of the taxon-specific differences in response are possibly associated with the possession of an effective carbon concentrating mechanism (CCM). These are widespread in diatoms [41], including sea ice diatoms [42], and have also been reported in some dinoflagellates [43,44]. However, it is not known whether a CCM is present in *Polarella glacialis*. Dinoflagellates are the only

phytoplankton group that possesses form II Rubisco, which is mostly associated with anaerobic phototrophic bacteria, and has a particularly low affinity for CO2 [44]. Without a CCM these organisms would experience growth-limiting concentrations of CO2 under current oceanic conditions [44] and for brine algae this would be exacerbated in the very high pH conditions often experienced in late spring and early summer. For *P. glacialis* to dominate these highly variable microenvironments, often with very low CO2 and O2 supersaturation, possession of an effective CCM would be highly likely.

Field studies in the Southern Ocean (Ross Sea) in an area of significant vertical mixing and Fe stress, however, showed a strong relationship between carbon uptake and elevated pCO2 [45]. They also found that elevated pCO2 caused changes in species composition promoting the growth of large diatoms. Similar community composition shifts were also seen in field experiments in the equatorial Pacific [46].

Plankton communities that are naturally exposed to large variations in pH and CO2 concentration, such as brine algae, seem to have a greater tolerance to these changes. This has also been seen, for instance, in some coastal communities of the Baltic Sea [12,13] and North Sea [14] where natural pCO2 varies seasonally between 500 μatm and 2500 μatm. These communities demonstrated a high degree of tolerance and showed only subtle changes to elevated pCO2.

Importantly, future marine phytoplankton communities will not only be exposed to decreases in pH but also to coincident increases in abiotic factors such as temperature and light (though increased stratification) and it will be important to consider the cumulative effect of multiple ocean drivers [34,47,48]. However, sea ice microbial ecosystems are less likely to experience the same changes in abiotic factors as phytoplankton; temperature for instance can never rise beyond 0°C and except for local variations in light caused by snow cover and ice thickness, there are not likely to be significant changes in available light. Including co-varying manipulations of light and/or temperature in the experiments reported here was therefore less relevant than in planktonic systems.

Several of the experimental treatments reported herein experienced a loss of chlorophyll biomass (reported as negative growth rates) during the incubations. The most likely explanation for these decreases is grazing as light and temperature conditions remained unchanged and there is evidence from elsewhere that carbon manipulations do not affect the cellular chlorophyll content [33,34,37]. There is, however, evidence that in some ecosystems changes in CO2 concentrations affects grazer-prey interactions [9]. Although meiofaunal abundance within sea ice, and within brine channels in particular, is very low [49,50], there are currently no published measurements of grazing rates. Change in chlorophyll biomass has often been used to measure growth in sea ice ecosystems (e.g. [51]) and there is an unstated assumption that grazing pressure remains constant. This assumption is probably reasonable in this study as incubation periods were relatively short.

The experiments documented here demonstrate that sea ice brine algal communities are tolerant to the changes in pH that are likely to be experienced by the end of the century and will possibly benefit from the associated increases in CO2. However, physiological responses and expression of CCM activity are variable between species and even between strains of the same species [44]. Also, the results reported here are based on short incubations and do not account for the ability of species and communities to adapt.
over longer time periods. It is probable that sea ice brine communities will not be adversely affected by OA.
