INTRODUCTION

The low mortality with cardiovascular disease in women is partly due to estrogen, which has many biologic effects including anti-atherogenic action. Phytoestrogen, a kind of soyprotein, has a weak but similar action with estrogen on atherosclerosis. Adlercreutz (1) suggests that populations that consume a high phytoestrogen diet have a lower risk of cardiovascular disease and cancer. The lower incidence of cardiovascular disease in Asian countries and in vegetarians suggests that phytoestrogens may be cardioprotective.

Genistein is a principal isoflavone found in soy phytoestrogen, and it has structural similarity with 17β-estradiol. Phytoestrogen shows many anti-atherogenic activities. It decreases cholesterol concentration (2), lowers blood pressure (3) and increase HDL cholesterol (4). Genistein inhibits vascular smooth muscle cell proliferation (5), improves arterial compliance (6, 7) and it has an antioxidant action (8, 9). Therefore, dietary phytoestrogen may be cardioprotective.

Studies of clinical events with atherosclerosis provide that plaque stability seems a more important factor than lesion size (10). Activated T lymphocytes in atherosclerotic lesion produce an inflammatory cytokine interferon-γ (IFNγ). IFNγ acts on vascular smooth muscle cells to decrease the synthesis of interstitial collagen (11, 12). IFNγ also inhibits smooth muscle cell proliferation (13), helping reduction of collagen synthesis in the atheromatous lesion. In addition, collagen breakdown by the proteolytic enzymes, such as metalloproteinases (MMP) family, further weaken the fibrous cap (14, 15).

Since macrophages and smooth muscle cells are major cells in atherosclerotic lesion, we are interested in the relationship between the dietary intake of genistein and composition of macrophages and smooth muscle cells in the lesion. In fact, lipid lowering reduces the number of macrophages in experimental atherosclerosis and stabilizes the plaques by reducing proteolytic activity (16, 17).

In this study, we investigated the effect of dietary genistein on hypercholesterolemic rabbits. We studied the effects of genistein supplementation on lesion progression, ratio of macrophages to smooth muscle cells using immunohistochemistry. We also measured matrix metalloproteinase-3 expression by western blotting in the aortic wall.

MATERIALS AND METHODS

Animals and diets

Twenty eight young male New Zealand White rabbits...
Experimental design

The aortas were removed and both proximal and distal 1 cm of the aorta were frozen by liquid nitrogen and stored at -80°C for molecular study. Others were fixed in 10% buffered formalin solution. Two sections of 0.5 cm-length each from the proximal, middle and distal portion (total 3 sections) were embedded in paraffin (Paraplast, Oxford, St. Louis, MO, U.S.A.) for light microscopy and immunohistochemistry. Sections taken from each artery were stained with Verhoeff-Van Gieson staining and evaluated for atherosclerotic lesion by image analyzer using Visus Image Analysis System (Image and Microscopy Technology, Korea). In short, we measured the round area consist of boundary line of the proximal, middle and distal portion (total 3 sections) and expressed as mean ± SD.

Immunohistochemistry

Sections taken from each artery were evaluated for RAM 11 (DAKO Corporation, Carpinteria, CA, U.S.A.) and HHF-35 (DAKO) expression using an each monoclonal antibodies. Simultaneous staining of slides from all groups has performed.

Table 1. Experimental design

| Groups       | Atherosclerosis | Progression (18 wk) |
|--------------|-----------------|---------------------|
| (rabbit number used) | provoking (17 wk) | or regression |
| Control (7)  | HD              | None                |
| I: Hypercholesterol diet (HD) (7) | HD | HD |
| II: HD + Genistein (7) | HD | HD + Genistein |
| III: HD + normocholesterol diet (ND) (7) | HD | ND |

HD, hypercholesterol diet; ND, normal diet.

Four μm-thick paraffin sections from the arteries were incubated with 3% hydrogen peroxide for five minutes, then with 0.5% casein-Tris buffer for thirty minutes for blocking non-specific binding. The slides were incubated with anti-RAM 11 and HHF-35 for two hours. After incubation with species appropriate biotinylated secondary antibodies (Vector Laboratories, Vectorstain ABC kit; Vector Laboratories, Burlingame, CA, U.S.A.) for 30 min, washed and incubated with streptavidin conjugated horseradish peroxidase (HRP) for 30 min. HRP visualization was carried out using 3,3'-diaminobenzidine tetrahydrochloride (ScyTek, Logan, Utah, U.S.A.) as substrate. Sections were counterstained with Light Green solution. Slides in which primary antibodies were omitted served as negative controls for each antibody used in this study.

The brown-stained areas by anti-RAM 11 and anti-HHF-35 antibodies were regarded as macrophages and smooth muscle cell, respectively, and measured by the image analyzer.

Western blotting

Each tissue were homogenized in ice-cold buffer of 50 mM Tris-HCl, pH 7.4/1 mM EDTA containing antipain (10 μg/mL), leupeptin (10 μg/mL), and phenylmethylsulfonyl fluoride (100 μg/mL), and centrifuged at 4°C, 12,000 rpm for 30 min and supernatant collected. Protein content in each sample was determined by a BioRad protein assay. Twenty μg of protein in each were removed and mixed with 6× sodium dodecyl sulfate (SDS) sample buffer (4× Tris-HCl/SDS pH 6.8, glycerol (20%), SDS (1%), bromophenol blue (1.2%), 3 M Urea). The sample mixture was boiled at 100°C for 5 min and loaded onto a 6% polyacrylamide mini-gel for SDS polyacrylamide gel electrophoresis (SDS-PAGE). Proteins separated on the minigel were transferred onto a nitrocellulose membrane with a Bio-Rad transfer system at 80 V for 1 hr. The membrane was blocked with 5% nonfat dry milk in PBS at room temperature for 1 hr and incubated at 4°C overnight with mouse monoclonal antibody against rabbit matrix metalloproteinase-3 (Oncogene, U.S.A.) diluted at 1:1,000 in blocking buffer. After washing with PBS containing 0.1% Tween-20, the membrane was incubated with a horseradish peroxidase-conjugated anti-rabbit IgG secondary antibody at room temperature for 1 hr. The membrane was washed with PBS, developed by an enhanced chemiluminescence (Amersham Pharmacia Biotech, Buckinghamshire, U.K.) western blot analysis system and exposed to Kodak XAR radiography film.

Statistical analysis

Statistical analysis was performed using Students’ t-test to evaluate difference between the sample of interest and its respective control.
RESULTS

Lesion development

The lesions were developed mildly during the provocation period (average: 0.269 mm²), however, no aortas revealed any gross or microscopic atherosclerotic lesion in the control group. On light microscopic examination, the lesions consisted of intimal hyperplastic lesion, which mainly composed of lipid-laden macrophages (foam cell) and smooth muscle cells. There were some variation of the lesions, but any fibrotic, calcific, or thrombotic plaque lesion was not demonstrated. No morphologic differences were demonstrated among experimental groups. All cholesterol-fed animals (ND, HD+G and HD group) had a lesion on the aortic endothelium (Fig. 1).

The lesion is progressed by continuous hyperlipidemic diet (average: 10.06 mm²), which is prevented partly by genistein (average: 0.997 mm²). Normal diet decreased the lesion size (average: 0.228 mm²).

The characteristic of atherosclerotic lesions

The immunohistochemistry for RAM-11 revealed diffuse positive reaction in foamy cells and histiocytes in the lesion (Fig. 2). The characteristic of the reaction was not different among three experimental groups. The reactions with HHF-35 antibody showed in the smooth muscle cells within the lesion (Fig. 3). However, the staining intensities were slightly weaker than RAM-11, although it revealed similar reaction among the experimental groups. The average areas of positive reaction to each antibody were measured by the image analyzer, and the ratio of RAM-11 to HHF-35 area was measured (Fig. 4). There was no difference of statistical significance between the experimental groups (p>0.05).

Western blotting for MMP-3

ND and HD+G groups show similar bands of intensity on Western blotting with MMP-3. However, HD group revealed stronger expression of MMP-3 (Fig. 5).

DISCUSSION

The genistein supplementation inhibits the atherogenesis and decreases the MMP-3 expression in the aorta. However, it has no or little effect on the ratio of macrophages/smooth muscle cells in the aortic atherosclerotic lesions.

Phytoestrogen has been known to have many anti-atherogenic actions as described in the introduction, but there are also some inconsistent reports on the action of phytoestrogen on blood lipid concentration. Probably that is originated from variable intestinal absorption in each experimental models.
Genistein Supplementation Inhibits Atherosclerosis

and/or different concentration of phytoestrogen in the diets or materials. However, phytoestrogen or estrogen may have bigger action in improving vascular functions than in just reducing cholesterol (19-22), and this is independent of estrogen’s action on plasma lipids (20). Therefore, such action may be a main mechanism in the decrease in ischemic heart disease in women treated with estrogen replacement (21).

Lipid peroxidation due to hyperlipidemic diet may be the predominant factor of endothelial injury in this hypercholesterolemic model. Therefore, the inhibition of the atherosclerotic lesion by genistein might be due to the improvement of the endothelial dysfunction with decreasing oxidative modification of LDL cholesterol. Squadrito et al. (23) showed that genistein supplementation improves endothelial dysfunction in ovariectomized rats.

It is now widely accepted that atherosclerosis is a chronic inflammatory process, and the lesion mainly consists of macrophages, lymphocytes, smooth muscle cells and extracellular matrix containing lipid (24, 25). Since genistein has anti-atherosclerotic action, it led us to hypothesize the genistein also inhibits the inflammatory process in atherogenesis. We have questioned whether genistein effects on the composition of histiocytes and/or smooth muscle cells in the lesion, because these two cell types are main part in atherosclerosis. But there was no difference between genistein addition and no addition groups on the two cell types, at least in the composition. Several explanations would be possible for these results. First, genistein has no direct effect on the macrophages-smooth muscle cells in the inflammation. Second, the effects of genistein on these two cells were similar.
It has been suggested that one of the mechanisms by which estrogen replacement therapy may reduce the cardiovascular risk among postmenopausal women is the improving vascular reactivity (20-22). Since estrogen receptors are present in the blood vessel wall (26), genistein is able to act as estrogen agonist on the tissue (27). Some researches about phytoestrogen showed that it improved arterial stiffness (28) and potentiated endothelium-dependent vasodilatation (7). Honore et al. (29) reported that isoflavone enhances coronary vascular reactivity in atherosclerotic female monkeys.

Teede et al. (30) proposed that the reduction in arterial stiffness by estrogen or phytoestrogen may be an important factor in the apparent reduction in cardiovascular risk as demonstrated in epidemiological studies. A significant number of acute thrombotic occlusion that develops between angiograms occur in arterial segments that were angiographically normal or mildly irregular in the first angiogram (31). Practically, the acute, often unheralded, onset of symptoms in acute myocardial infarction suggests that pre-existing coronary stenoses susceptible to acute thrombotic occlusion in the infarct-related artery may not necessarily have been severe (32). In addition, the vulnerable plaques occur across the full spectrum of severity of stenosis, and disruption of a plaque causing minimal stenosis is more likely to invoke an acute ischemic episode because of the lack of prior collateral development (33). Rioufol et al. (34) suggested that the acute coronary syndrome is more connected with overall coronary instability rather than one single lesion when observed by their intravascular ultrasound study. Therefore, the character of the atherosclerotic lesions may be more important than the size itself.

Aikawa et al. (35) demonstrated that lipid lowering by dietary manipulation significantly reduces proteolytic activity and increases collagen content of established atheroma in rabbits, when MMP-1 activity was measured. Bocan et al. (36) showed that MMP expression was reduced by cholesteryl esterification enzyme inhibitor. Their results suggested that lipid lowering may stabilize vulnerable plaques by reduced activity of the enzymes that degrade the arterial extracellular matrix, and render atheroma less susceptible to disruption and thrombosis by favoring collagen accumulation in the fibrous cap. In fact, with atherosclerotic lesion development, the expression of matrix metalloproteinase-1, -3, -7, and 9 increase (37, 38).

In this experiment, we could see decreased MMP-3 expression in the aorta in genistein supplementation and lipid lowering rabbits. The increased expression of the enzyme may contribute to stabilization of the lesion, since the enzyme involved in plaque rupture in the advanced lesion.

We conclude that genistein, a type of phytoestrogen, inhibits aortic atherosclerosis initiated by hyperlipidemic diet in rabbits. The mechanism for this lesion inhibition might be due to decrease endothelial dysfunction by inhibiting oxidative modification of LDL cholesterol, rather than direct action on macrophage or smooth muscle cells in the atherosclerotic lesion.

The results also suggest that genistein may represent a good candidate to substitute estrogens in the prevention of atherosclerosis for stabilization of the atherosclerotic lesion. We think further studies are needed for understanding of mechanism of anti-atherogenic action of phytoestrogen.
