Motivated by the realization of spin-valley Hubbard model on a triangular moiré superlattice in ABC trilayer graphene aligned with hexagon boron nitride (hBN) and possibly also in twisted transition metal dichalcogenide homobilayers, we study possible Mott insulating phases and pseudogap metals based on symmetry constraint and parton mean field theories. First, we show that the Luttinger constraint allows two distinct symmetric and featureless Fermi liquids when there is an intervalley Hund’s term breaking SU(4) spin rotation. Especially, there exists a symmetric and featureless “pseudogap metal” with small Fermi surfaces. Then, we suggest to search for such an unconventional metallic state by doping the Mott insulator at $\nu_T = 2$. For this purpose, we study the $\nu_T = 2$ Mott insulator using the SO(6) Schwinger boson or Schwinger fermion parton. At the SU(4)-symmetric point, we find two symmetric $Z_2$ spin liquids. With a large anti-intervalley Hund’s term, a featureless Mott insulator is natural. Next, we show that doping the featureless Mott insulator or a $Z_2$ spin liquid can lead to featureless or orthogonal “pseudogap metal” with small Fermi surfaces proportional to the doping. Besides, we also provide one scenario for the evolution from pseudogap metal to the conventional Fermi liquid through an intermediate exotic “deconfined metal” phase. Last, we give brief comments on the possibility of U(1) spinon Fermi surface state or $Z_2$ spin liquid at $\nu_T = 1$.

1. INTRODUCTION

Recently, moiré superlattices from Van der Waals heterostructures emerge to be a wonderful platform to study strongly correlated physics. These include correlated insulator [1], superconductivity [2–4], and anomalous Hall effect [5] in twisted bilayer graphene, spin-polarized correlated insulators [6–8], and superconductivity [6,7] in twisted bilayer-bilayer graphene. In addition, ABC trilayer graphene aligned with a hexagonal boron nitride (TLG-hBN) has been demonstrated to host gate-tunable correlated insulator [9], superconductor [10], and Chern insulator [11].

Theoretically, it has been shown that both bandwidth and band topology can be tuned by the displacement field in the TLG-hBN system [12,13]. For one sign of displacement field, the valence bands from the two valleys have nonzero and opposite Chern numbers. Similar narrow Chern bands have also been predicted in twisted bilayer graphene aligned with hBN [14,15] and in twisted bilayer-bilayer graphene [12,16–20]. These systems therefore may realize interesting “quantum Hall” physics. Indeed, anomalous Hall effect [5] and Chern insulator with $\sigma_{xy} = 2x$ [11] have already been reported. In contrast, for the other sign of displacement field in TLG-hBN, the valence band is trivial and there is no obstruction to build lattice models from constructing Wannier orbitals [21]. Such a spin-valley Hubbard model on triangular lattice is derived in Ref. [22]. $\nu_T$ in this Hubbard model can be tuned by the magnitude of the displacement field. Therefore, the trivial side of TLG-hBN offers an amazing platform to study Hubbard model physics [22–26], which may be similar to that of the cuprates. The observation of a superconductor in the trivial side [10] is encouraging. In cuprates, the pseudogap metal and the strange metal remain as an unsolved mystery in addition to the high-$T_c$ superconductor. Then, a natural question is as follows: Can TLG-hBN also host similar “pseudogap metal” and “strange metal” phases? In this paper, we try to give a positive answer to this question by explicitly constructing several simple pseudogap metal Ansätze in the spin-valley Hubbard model. A SU(4) Hubbard model on triangular lattice may also be realized in twisted transition metal dichalcogenide (TMD) homobilayer [27]. Therefore, our discussions can also be relevant to future experiments in twisted TMD bilayers.

In cuprates, a sensible theoretical scenario is that the strange metal is associated with a quantum critical point between the pseudogap metal and the conventional Fermi liquid (FL). However, the critical point, even if exists, is covered by the superconducting phase. When the superconductor is suppressed by strong magnetic field, in the underdoped region experiments observe signatures of small Fermi surfaces through quantum oscillation [28] and Hall measurement [29]. The area of the small Fermi pocket inferred from the experiment is proportional to the doped additional holes instead of all of the electrons. It is still under debate whether this high-field pseudogap metal is from some density wave orders [30,31] or is from a symmetric metal like fractionalized Fermi Liquid (FL*) phase [32,33]. As a matter of principle, density wave order parameter is not necessary to gap out Fermi surface and there should exist a symmetry pseudogap metal with small Fermi surfaces once fractionalization is allowed. However, we do not know any simple model so far to realize these symmetric metals with small Fermi surfaces. In this paper we will show that the spin-valley Hubbard model is very promising in this direction. More specifically, we show that at filling $\nu_T = 2 - x$, there are naturally symmetric pseudogap metals with Hall number $\eta_H = -x$. Depending on the value of intervalley Hund’s coupling, the pseudogap metal is either a featureless Fermi liquid or an orthogonal metal [34].
We can understand the existence of pseudogap metals from two different perspectives. First, with an intervalley Hund’s term, the U(4) symmetry is broken down to [U(1) × U(1)] val × SU(2) spin /Z2. Then, the Lieb-Schultz-Mattis (LSM) constraint allows two distinct symmetric and featureless Fermi liquids with Fermi-surface areas AFS = 2π2/3 or AFS = −2π2/3. In the second perspective, symmetric pseudogap metals can be constructed from doping-symmetric Mott insulators. Therefore, we turn to study the possible symmetric Mott insulators at νF = 2. Depending on the value of intervalley Hund’s coupling JH, we find a featureless insulator and two symmetric Z2 spin liquids using SO(6) Schwinger boson or Schwinger fermion parton construction. Then, within a SO(6) slave-boson parton theory, doping the Mott insulator leads to a featureless Fermi liquid or an orthogonal metal. Both of them have small Fermi surfaces with area equal to π, resembling experimental results of underdoped cuprates. This valley-dependent flux on the Fermi surface determines the possibility of pseudogap metals. If the intervalley Hund’s coupling is much larger than the hopping on the same bond), the charge is localized and the low charge gap metals can be constructed from doping-symmetric Mott insulator at νF = 2. At integer νF = 1 and 2, in the SU(4)-symmetric limit, we have

\[ H_S = J \sum_{ij} \sum_p S_i^p S_j^p \] (2)

with \( J = \frac{2J}{T_0} \), \( S_i^p \), with \( p = 1, 2, \ldots, 15 \), is a spin operator on each site. These 15 spin operators can be simultaneously transformed as \( S_{ij}^{\mu \nu} = \tau^{\mu \nu} a^\dagger \sigma_{\nu} \) with \( \mu, \nu = 0, 1, 2, \ldots, 5 \). Each is a fermion bilinear:

\[ S_i^{\mu \nu} = \sum_{a_1, a_2, a_3, a_4} c_{a_1 a_2, a_3, a_4} \tau_{a_1 a_2}^{\mu} \sigma_{a_3}^{\nu} c_{a_3 a_4, a_2 a_1}. \] (3)

Projecting to the four- and six-dimensional Hilbert space at each site for \( \nu_F = 1, 2 \), \( S_i^{\mu \nu} = \tau^\mu a^\dagger \sigma^\nu \) should be viewed as 4 × 4 and 6 × 6 matrices for \( \nu_F = 1 \). The spin Hamiltonian has PSU(4) = SU(4)/Z4 symmetry. Here, Z4 means the global U(1) transformation \( e^{i \theta_n} \) with \( n \) as an integer. At \( \nu_F = 2 \), each site is in the 6d-irrep of SU(4), which transforms as SO(6) fundamental under SU(4) [SO(6) ≃ SU(4)/Z2].

For the TLG-hBN system, there is a valley-contrasting phase in the hopping term [22]. Two valleys have opposite staggered flux patterns. This valley-dependent flux on the hopping term is inherited in the \( t^2/\bar{U} \) expansion and gives an anisotropy term

\[ H_F' = J \sum_{(ij)} \cos 2\phi_{ij} - 1)(\tau^x_i \tau^y_j + \tau^y_i \tau^z_j)(1 + \sigma_i \cdot \sigma_j) + J \sum_{(ij)} \sin 2\phi_{ij} (\tau^x_i \tau^x_j - \tau^y_i \tau^y_j)(1 + \sigma_i \cdot \sigma_j), \] (4)

where \( \phi_{ij} \) is the phase in the hopping for the valley + on bond (ij) (correspondingly, the valley − has phase −\( \phi_{ij} \) for the hopping on the same bond).

II. HAMILTONIAN AND SYMMETRY

A lattice model for TLG-hBN has been derived in Ref. [22]. To leading order it is a spin-valley model on triangular lattice:

\[ H = -t \sum_a \sum_{(ij)} e^{i \phi_{ij}} c^\dagger_{ai} c_{aj} + H.c. \]

\[ + \left( \frac{J}{2} n_i^z + J_H \sum_i \mathbf{S}_{+4} \cdot \mathbf{S}_{-4} \right). \] (1)

where \( a = +, - \) is the valley index. We have suppressed the spin index. \( U \) is the Hubbard interaction and \( J_H \) is an onsite intervalley spin-spin coupling. \( \phi_{ij} = -\phi_{ij} \) provides the valley-contrasting staggered flux pattern.
FIG. 1. Two distinct $t$-$J$ models in four-flavor spin-valley Hubbard model. $\nu < 2$ and $\nu > 2$ are related by particle-hole transformation. $\nu_T < 1$ and $1 < \nu_T < 2$ realize two essentially different $t$-$J$ models.

The above symmetry breaks the PSU(4) spin rotation down to SO(3)$_+$ $\times$ SO(3)$_-$ $\times$ U(1)$_r$. For $\nu_T = 2$ the corresponding spin rotation symmetry can be viewed as U(1)$_r$ $\times$ SO(4)/Z$_2$ $\cong$ SO(3)$_+$ $\times$ SO(3)$_-$ $\times$ U(1)$_r$, where SO(4) acts on the 4d space formed by three valley singlet, spin triplet and one valley triplet, spin singlet.

For $\nu_T = 2$, there is an additional onsite intervalley spin-spin coupling:

$$H''_S = J_H \sum_i \vec{S}_i^+ \cdot \vec{S}_i^-.$$  \hspace{1cm} (5)

We define the valley-specified spin operator

$$\vec{S}_i^a = \frac{1}{2} \sum_{\sigma_i, \sigma_{i+1} = \uparrow, \downarrow} e^{\frac{i}{2} \sigma_{i+1} a} \vec{\sigma}_{i+1} e^{\frac{i}{2} \sigma_i a}$$  \hspace{1cm} (6)

for $a = +, -$. $H''_S$ vanishes for $\nu_T = 1$. For $\nu_T = 2$, it further breaks the spin rotation symmetry down to U(1)$_{valley}$ $\times$ SO(3)$_{spin}$.

B. Finite doping: Type I and II $t$-$J$ models

In spin-$\frac{1}{2}$ Hubbard model, the physics at finite doping away from the Mott insulator is believed to be governed by a $t$-$J$ model at the $U \gg t$ limit. Here we want to show that for the spin-valley Hubbard model, the region $1 < \nu_T < 2$ has different physics from the traditional $t$-$J$ model in the region $0 < \nu_T < 1$. Therefore, the four-flavor Hubbard model can actually realize two distinct $t$-$J$ models, which is illustrated in Fig. 1.

1. $\nu_T = 1 - x$: Type I $t$-$J$ model

At filling $\nu_T = 1 - x$ with $0 < x < 1$, the low energy is described by a similar $t$-$J$ model as in the spin-$\frac{1}{2}$ case:

$$H = -t \sum_{\langle ij \rangle} (P_i + P_d^a) c_{i}^{\dagger} c_{j} + J \sum_{\langle ij \rangle} S^a_i S^a_j + H''_S,$$  \hspace{1cm} (7)

where $P_i$ is the projection operator which forbids states with $n \geq 2$ on each site.

For $\nu_T = 1 - x$, the onsite intervalley spin-spin coupling $J_H$ term vanishes in the leading order of $t/U$ because of the restriction of the Hilbert space. It enters in the second order of $t/U$ by changing the spin coupling from $t^2/U$ to $t^2/2J_H$. The change of the spin coupling is $\delta J \sim J_H/t \ll J$ and can be ignored given the estimation that $J_H \sim 0.01U$ [22]. Therefore, there is an approximating U(2)$_+ \times$ U(2)$_-$ symmetry at the $U \gg t$ limit even if $J_H \neq 0$.

In this type I $t$-$J$ model, each site is either empty or singly occupied, similar to that of hole-doped cuprate [37]. For convenience, in this paper we call the empty site as holon and the singly occupied site as singlon (see Fig. 2). The Hilbert space dimension of the holon, singlon, doublon states are 1, 3, and 6, respectively.

In type I $t$-$J$ model, each site is either empty or singly occupied, similar to that of hole-doped cuprate [37]. For convenience, in this paper we call the empty site as holon and the singly occupied site as singlon (see Fig. 2). The Hilbert space dimension of the holon, singlon, doublon states are 1, 3, and 6, respectively.

2. $\nu_T = 2 - x$: Type II $t$-$J$ model

At filling $\nu_T = 2 - x$ with $0 < x < 1$, we have either a singlon or a doublon state at each site in the $U \gg t$ limit. Thus, the Hilbert space dimension at each site is $4 = 10$. In addition, the singlon and the doublon carry different representations of SU(4) spin. Hence, there are three different spin couplings (see Fig. 3). We define $P_s$ and $P_d$ as the projection operators to the singlon and the doublon states, respectively. Then, it is natural to have spin operators for the singlon and doublon: $S^{\mu \nu}_{i s} = P_s S^{\mu \nu}_{i s} P_s$ and $S^{\mu \nu}_{i d} = P_d S^{\mu \nu}_{i d} P_d$. We have the type II $t$-$J$ model as

$$H = -t \sum_{\langle ij \rangle} (P_s + P_d) c_{i}^{\dagger} c_{j} + J \sum_{\langle ij \rangle} S^a_i S^a_j + H''_S$$

$$+ \frac{1}{2} J' \sum_{\langle ij \rangle} (S^a_{i d} S^a_{i d} + S^a_{i d} S^a_{i s})$$

$$+ J_d \sum_{\langle ij \rangle} S^a_{i d} S^a_{i d} + H''_S,$$  \hspace{1cm} (8)

where $J' = \frac{1}{2} J$ and $J_d = J$. In the superexchange process involving a singlon and a doublon nearby, the only process

FIG. 2. Label of several different states according to the number of particle $n$, at the site. Holon is an empty site. Singlon and doublon are in the fundamental rep and the SO(6) rep of the SU(4) group, respectively. The Hilbert space dimensions of the holon, singlon, doublon states are 1, 3, and 6, respectively.

FIG. 3. Illustration of the type I and II $t$-$J$ models. In type II model, there are three different spin-spin couplings.
we should keep is to hop the particle from the singlon to the doublon, which costs energy $2U$ instead of $U$. This is how the two factors $\frac{1}{2}$ arise. Because of the $H^c$ term, generically we only have $U(2) \times U(1)_{\text{valley}}$ spin rotation symmetry.

The two $t$-$J$ models in Eqs. (7) and (8) are apparently quite different. In the type II $t$-$J$ model, there is no empty site in the Hilbert space. Instead, the singlon and doublon both carry spin. The kinetic term now becomes the exchange of the $t$ in the Hilbert space. Instead, the singlon and doublon both carry spin. The kinetic term now becomes the exchange of the $t$-spin instead of $v$. This $t$-$J$ model can be derived from the SU(4)-symmetric $t$-$J$ model in this paper by adding anisotropic terms. Therefore, our analysis in this paper may also provide insights to the solid-state realization of type II $t$-$J$ model using the two $e_g$ orbitals.

In the familiar $t$-$J$ model, at least for large doping, the most natural ground state is a conventional Fermi liquid. This state can be constructed within the simple slave-boson mean field theory [37] which respects the constraint $P_1$. The simple way to understand this Fermi-liquid state is that the holons condense and the singlons form Fermi surfaces. This picture can be easily generalized to the case $\nu_T = 1 - x$ for the spin-valley Hubbard model. However, for $\nu_T = 2 - x$, neither the singlons nor the doublons can form Fermi surfaces whose areas match a conventional Fermi liquid. In this case, description of a conventional Fermi liquid is very hard if we insist to respect the constraint $P_2$. As we show later, a generalized slave-boson mean field theory naturally predicts pseudogap metals with Fermi-surface areas proportional to $x$ instead of $\nu_T$. We can still describe a conventional Fermi-liquid phase, but it requires a more exotic parton construction if we want to respect the constraint $P_2$.

### III. SYMMETRY CONSTRAINT: LUTTINGER THEOREM

Before we move to discussions of specific fillings, we give a general symmetry analysis in this section. We will consider LSM type of constraints based on the simple Oshikawa-flux threading argument [40]. The argument and the constraint works for both integer and incommensurate filling. Besides, the symmetry analysis in this section is independent of models and also applies to the case with topological bands.

The symmetries that we consider here are translation, spin rotation, charge conservation, and time reversal. Depending on whether we include the intervalley spin-spin coupling, we consider $U(2)_+ \times U(2)_-$ spin rotation symmetry and $U(1)_c \times U(1)_v \times \text{SO}(3)_v$ separately. In all cases we assume there is a time-reversal symmetry which exchanges the two valleys.

#### A. Symmetry $U(4)$ or $U(2)_+ \times U(2)_-$

The constraint is the same for $U(4)$ and $U(2)_+ \times U(2)_-$. For simplicity, we will only use $U(2)_+ \times U(2)_-$. Note that time reversal exchanges two valleys so the density for each flavor is guaranteed to be $\nu = \frac{\nu_T}{2}$. Meanwhile, we have $U(1)^4 \subset U(2)_+ \times U(2)_-$, which means we have $U(1)$ symmetry for each flavor. Then, we can do flux insertion for one valley-spin species out of four. Using Oshikawa’s argument [40], one can reach the conclusion that any symmetric and featureless phase needs to have Fermi-surface area $A_{FS} = v\text{mod}n = \frac{v_T}{2}\text{mod}n$, where $n$ is an integer.

For $\nu_T = 1, 2$, the above constraint means there must be a Fermi surface with area $\frac{1}{4}$ or $\frac{1}{2}$ for each flavor. Therefore, a symmetric and featureless Mott insulator is not possible for symmetry $U(2)_+ \times U(2)_-..$

#### B. Symmetry $[U(1)_c \times U(1)_v \times SU(2)_s]/Z_2$: Two distinct symmetric and featureless states

When there is a nonzero $J_H$, the global symmetry is $[U(1)_c \times U(1)_v \times SU(2)_s]/Z_2$. There is no separate spin rotation symmetry for each valley. Only the total spin rotation is conserved in this case. There are only three independent $U(1)$ global symmetries (corresponding to $N, S_z$, and $\tau_z$) that belong to $[U(1)_c \times U(1)_v \times SU(2)_s]/Z_2$. [Recall that there are four $U(1)$ charges in the previous subsection.] Gauging these three $U(1)$ symmetries yields three independent flux insertions. We cannot do flux insertion for each valley-spin species. The best we can do is to include at least two valley-spin species in the flux insertion process in order to respect the global symmetry. Since we still have time-reversal and total spin rotation symmetry, the filling per valley per spin is still fixed to be $\nu = \frac{\nu_T}{2}$, $\nu_T$ being the total filling. If the ground state is a symmetric Fermi liquid, the Fermi-surface area for every flavor must be equal to each other. Let us perform an adiabatic $U(1)$ flux insertion for both spins of the + valley. The constraint one can get using Oshikawa’s argument is $A_{FS,+1} + A_{FS,+1} = 2A_{FS} = v_{+1} + v_{+1}\text{mod}n = \frac{v_T}{2}\text{mod}n$, where $n$ is an integer. This yields $A_{FS} = \frac{v_T}{4}\text{mod}m$ or $A_{FS} = (\frac{v_T}{4} - \frac{1}{2})\text{mod}m$, where $m$ is an integer.

Interestingly, we find that there are two distinct symmetric and featureless Fermi liquids. One of them is connected to the free-fermion model while the other one has smaller Fermi surfaces and may be viewed as a “pseudogap metal.” The essential point of the argument is that there are only three $U(1)$ charges while there are four flavors. Meanwhile, the symmetry is sufficient to forbid bilinear term with interflavor coupling and guarantee four equal Fermi surfaces. The above two conditions can not be satisfied simultaneously in the traditional spin-$\frac{1}{2}$ system. This is a special feature of spin-valley model realized in moiré superlattices.

At $\nu_T = 2$, we are allowed to have $A_{FS} = \frac{1}{4}$ or $A_{FS} = 0$, which implies the existence of a symmetric and featureless Mott insulator. We need to emphasize that $U(1)_c$, and time-reversal symmetry is important to guarantee the existence of the two distinct classes. Without time reversal, we can have a “band insulator” at $\nu_T = 2$ by polarizing valley. This band insulator can smoothly connect to the conventional Fermi liquid by reducing the $\tau_z$ polarization. Once we have time-reversal symmetry, the density of each flavor is fixed to be $\frac{1}{2}$ at $\nu_T = 2$. In this case, the featureless Mott insulator can not smoothly cross over to the conventional Fermi liquid and can not be described by mean field theory with any order parameter.

We will construct both the featureless insulator at $\nu_T = 2$ and the featureless pseudogap metal in Secs. V and VII for the spin-valley Hubbard model. The essential physics behind
them is singlet formation. At $\nu_T = 2$, there are $N$ electrons in the valley + and $N$ electrons in the valley −, where $N$ is the number of moiré unit cells. These electrons can be gapped out by forming intervalley singlets. If we further dope electrons or holes with density $x$, these additional doped carriers just form small Fermi surfaces with area $A_{FS} = \frac{x}{4}$ on top of the featureless Mott insulator.

Although the picture of the featureless insulator and the featureless pseudogap metal is very simple, they cannot be described by the conventional mean field theory with symmetry-breaking order parameters. In the cuprate context, symmetric pseudogap metals with small Fermi surfaces have been proposed before [32,33]. In the so-called FL* phase, additional holes form small Fermi surfaces on top of a $\mathbb{Z}_2$ spin liquid. The physics behind is still singlet formation: $N$ number of electrons form resonating valence bond (RVB) singlets and the additional holes move on top of the RVB singlets. The difference in our case is that we can have onsite intervalley singlets and do not need to invoke fractionalization. In this sense, the featureless pseudogap metal we propose here is the simplest version of a symmetric pseudogap metal.

This simple symmetric pseudogap metal is beyond any conventional mean field theories with symmetry breaking because the singlet formation does not break any symmetry. So, how do we describe the singlet formation? It turns out that the singlet formation can be captured in a simple six-flavor slave-boson parton mean field theory. We will introduce the parton construction for the $\nu_T = 2$ Mott insulator first and then generalize it to the doped case to describe the featureless pseudogap metal. This slave-boson parton also allows us to describe another orthogonal pseudogap metal in the SU(4)-symmetric limit.

### IV. PROJECTIVE SYMMETRY GROUP ANALYSIS

#### A. Hilbert space

At $\nu_T = 2$, the Hilbert space is six dimensional at each site. There are six bases: $|\alpha\rangle = \sum_{ab} A^\alpha_{ab} c_a^\dag c_b^\dag |0\rangle$ with $\alpha = 1, 2, 3, 4, 5, 6$. $A^\alpha$ is a $4 \times 4$ antisymmetric matrix. We define the SU(4) flavor as $1: + \uparrow, 2: + \downarrow, 3: - \uparrow, 4: - \downarrow$. Each basis $\alpha$ is created by an operator $\Psi_\alpha^\dag$. We can define the following six bases:

\[
\begin{align*}
\psi_1 &= \frac{1}{2 \sqrt{2}} e^{T} \tau_x \sigma_y c = \frac{i}{\sqrt{2}} (-\Phi_{12} + \Phi_{34}), \\
\psi_2 &= \frac{1}{2 \sqrt{2}} e^{T} i \sigma_y c = \frac{1}{\sqrt{2}} (\Phi_{12} + \Phi_{34}), \\
\psi_3 &= \frac{1}{2 \sqrt{2}} e^{T} \tau_x \sigma_y c = \frac{i}{\sqrt{2}} (-\Phi_{14} + \Phi_{23}), \\
\psi_4 &= \frac{1}{2 \sqrt{2}} e^{T} i \tau_x \sigma_y c = \frac{1}{\sqrt{2}} (\Phi_{14} + \Phi_{23}), \\
\psi_5 &= \frac{1}{2 \sqrt{2}} e^{T} i \tau_x \sigma_y c = \frac{1}{\sqrt{2}} (\Phi_{13} - \Phi_{24}), \\
\psi_6 &= \frac{1}{2 \sqrt{2}} e^{T} \tau_x c = -\frac{i}{\sqrt{2}} (\Phi_{13} + \Phi_{24}).
\end{align*}
\]

where $\Phi_{ab} = \frac{1}{2} (c_a^\dag c_b - c_b^\dag c_a)$. These six states are organized to have clear physical meaning: the first three are valley triplet and spin singlet, while the latter three are valley triplet and spin triplet.

Let us define $\Psi^T = (\psi_1, \psi_2, \psi_3, \psi_4, \psi_5, \psi_6)$. It can be proved that the transformation is $\Psi^T = O \Psi'$ under the microscopic SU(4) transformation. $O$ is a SO(6) matrix. There are 15 generators for the SO(6). We list them in Table I. The physical spin operator $S^{\mu \nu}$ defined in Eq. (3) can be written as a $6 \times 6$ matrix in the above basis. It is convenient to express it as $S^{\mu \nu} = \Psi^A a^{\mu \nu} \Psi$. It turns out that the $6 \times 6$ matrix $A^{\mu \nu}$ only has two nonzero matrix elements. More specifically, each spin operator $S^{\mu \nu}$ corresponds to a $(\alpha, \beta)$ pair as listed in Table I. Then, $S^{\mu \nu} = \gamma^{\alpha \beta} = 2(\psi_4^\dag \psi_\beta - \psi_\beta^\dag \psi_4)$. For example, $\tau^+ = 2(i \psi_1^\dag \psi_2 - \psi_2^\dag \psi_1)$.

When $H'_c = H'_c^0 = 0$, the spin model has SO(6)/Z2 symmetry where $Z_2$ consists of the $6 \times 6$ matrix $-I$. When $H'_c \neq 0$, the spin rotation symmetry is $[\text{SO}(2) \times \text{SO}(4)]/\mathbb{Z}_2$. The Hilbert space at each site is decomposed to $6 = 2 \oplus 4$. $(\psi_1, \psi_2)$ transforms as SO(2) corresponding to U(1)$_{\text{valley}}$. $(\psi_3, \psi_4, \psi_5, \psi_6)$ transforms as SO(4) under SU(2)$_{\text{valley}} \times$ SU(2)$_{\text{spin}}$. If we further add the onsite intervalley spin coupling $H'_c^y$, the spin rotation symmetry is further reduced to SO(2)\times SO(3). The Hilbert space at each site is decomposed to three irreducible representations: $6 = 1 \oplus 2 \oplus 3$. $\psi_3$ forms a trivial representation. $(\psi_1, \psi_2)$ transforms under SO(2), and $(\psi_4, \psi_5, \psi_6)$ transforms under SO(3) in the same way as a spin-one degree of freedom.

For spin rotation symmetry SO(6)/Z2 and [SO(2)\times SO(4)]/Z2, there is no symmetric gapped state. For the symmetry SO(2)\times SO(3), a featureless insulator is possible. For example, the state $\prod_i |\psi_1^i\rangle |0\rangle$ is a featureless Mott insulator. However, we need a large $J_H$ to favor this featureless insulating phase. In the trilayer graphene/hBN system, we expect $|J_H|$ to be smaller or at most comparable with $J$. When $J \gg |J_H|$, other phases including magnetic order, valence bond solid (VBS), and spin liquids may be favored. In this paper we try to classify all of possible symmetry spin-liquid phases based on the projective symmetric group (PSG) analysis.

#### B. Parton theories at $\nu_T = 2$

For $\nu_T = 2$, there are three different parton theories which we introduce in this section.

1. Abrikosov fermion

The first parton theory is the Abrikosov fermion parton which has been widely used in the treatment of spin-$\frac{1}{2}$ systems. We introduce fermionic operator $f_{i\alpha}^\dag$ with $\alpha = 1, 2, 3, 4$.
The constraint is $\sum_{\alpha} f_{i\alpha}^\dagger f_{i\alpha} = 2$. There is a U(1) gauge structure. As we will discuss later, the only symmetric spin liquid from the Abrikosov fermion parton is $\bar{U}(1)$ spin liquid with four Fermi surfaces, each at filling $\frac{1}{2}$.

2. Six-flavor Schwinger boson

Because the Hilbert space at each site is six-dimensional and forms the fundamental representation of SO(6), we can use a six-flavor Schwinger boson parton construction. Basically, we identify $\Psi_\alpha$ in Eq. (9) as a bosonic operator $b_\alpha$, where $\alpha = 1, 2, \ldots, 6$. Correspondingly, the spin operator $S^{\alpha\beta} = 2i(b^\dagger_\alpha b_\beta - b^\dagger_\beta b_\alpha)$. For simplicity, we define a six-dimensional spinor $B(r) = (b_1(r), b_2(r), b_3(r), b_4(r), b_5(r), b_6(r))$. The constraint is $B^\dagger(r)B(r) = 1$ for each site $r$. The gauge structure is U(1).

We define hopping term $\tilde{T}_{ij} = B^\dagger_i B_j$ and $\tilde{\Delta}_{ij} = \frac{1}{\sqrt{2}}(B^\dagger_i B_j + B^\dagger_j B_i)$. $\tilde{T}_{ij} = T_{ij}$, $\tilde{\Delta}_{ij} = \frac{1}{\sqrt{2}}(B^\dagger_i B_j^T + B^\dagger_j B_i^T)$. Apparently, $\tilde{\Delta}_{ij} = \tilde{\Delta}_{ji}$.

The Hamiltonian in the SO(6) invariant limit can be written as

$$H = 4J \sum_{(ij)} \tilde{T}_{ij} \tilde{T}_{ji} - 4J \sum_{(ij)} \tilde{\Delta}_{ij}^\dagger \tilde{\Delta}_{ji}. \quad (10)$$

In the Schwinger boson theory, a typical mean field Ansatz is

$$H_M = \sum_{(ij)} (T_{ij} T_{ji}^\dagger + \Delta_{ij}^\dagger \Delta_{ji}). \quad (11)$$

where $T_{ij}$ and $\Delta_{ij}$ are mean field parameters. For Schwinger boson, the meaningful Ansatz has $\Delta_{ij} \neq 0$, which describes a Z2 spin liquid.

3. Six-flavor Schwinger fermion

Similar to the six-flavor Schwinger boson approach, we can also identify each basis $|\alpha\rangle$ in Eq. (9) to be created by a fermionic operator $\Psi_\alpha$. Defining $\Psi = (\Psi_1, \Psi_2, \Psi_3, \Psi_4, \Psi_5, \Psi_6)$. The constraint is $\Psi^\dagger(r)\Psi(r) = 1$ for each site $r$. The gauge structure is O(2) = $Z_2 \times U(1)$. $Z_2$ corresponds to a charge conjugation $C : \Psi(r) \rightarrow \Psi^\dagger(r)$. We define hopping term $\tilde{T}_{ij} = \Psi_j^\dagger \Psi_i$ and $\tilde{\Delta}_{ij} = \frac{1}{2}(\Psi_j \Psi_i^\dagger - \Psi_i \Psi_j^\dagger)$. Apparently, $\tilde{\Delta}_{ij} = -\tilde{\Delta}_{ji}$.

The SO(6) invariant Hamiltonian can be written as

$$H = -4J \sum_{(ij)} \tilde{T}_{ij} \tilde{T}_{ji} - 4J \sum_{(ij)} \tilde{\Delta}_{ij}^\dagger \tilde{\Delta}_{ji}. \quad (12)$$

The typical mean field Ansatz in the Schwinger fermion approach is

$$H_M = \sum_{(ij)} (T_{ij} T_{ji}^\dagger + \Delta_{ij}^\dagger \Delta_{ji}), \quad (13)$$

where $T_{ij}$ and $\Delta_{ij}$ are mean field parameters. For Schwinger fermion parton theory, we can have both U(1) spin liquid with $\Delta_{ij} = 0$ and Z2 spin liquid with $\Delta_{ij} \neq 0$. If $\Delta_{ij}$ is chiral, we can also have chiral spin liquid.

C. PSG classification of U(1) spin liquids at $\nu_T = 2$

We first discuss the U(1) spin liquid. There are two different kinds of U(1) spin-liquid phases. One is constructed from the Abrikosov fermion and the other one is constructed from the Schwinger fermion. For both Abrikosov fermion and Schwinger fermion, symmetry U(1) spin liquids have the same classification as shown in Appendix B. Both zero-flux phase and $\pi$-flux phase are symmetric. However, nearest-neighbor and next-nearest-neighbor hoppings in the $\pi$-flux phase are forbidden by the PSG, which is not physical. Therefore, we only consider the zero-flux phase for both the Abrikosov fermion parton and the Schwinger fermion parton.

From the Abrikosov fermion, we have a U(1) spin liquid with four Fermi surfaces, each of which is at filling $\frac{1}{2}$. This spin-liquid phase can go through a continuous transition to Fermi liquid. Basically, one can write the electron operator as $c_{i\alpha} = e^{i\theta_i} f_{i\alpha}$ and let the bosonic rotor go through a continuous superfluid-Mott transition [41].

From the Schwinger fermion, we have a U(1) spin liquid with six Fermi surfaces, each of which is at filling $\frac{1}{5}$. This U(1) spinon Fermi-surface phase is not connected to the Fermi liquid through direct transition.

D. PSG classification of Z2 spin liquids at $\nu_T = 2$

We then classify symmetric Z2 spin liquids at $\nu_T = 2$. The Z2 spin liquid can be constructed from both the Schwinger boson parton and the Schwinger fermion parton. The PSG is the same for both Schwinger boson and Schwinger fermion parton constructions. It is independent of the spin rotation symmetry and therefore is true even if the SO(6)/Z2 spin rotation is broken down to SO(2) × SO(3).

PSG classification is the same as the spin-$\frac{1}{2}$ Schwinger boson approach, and we can just quote the results of Wang et al. in Ref. [42]. The PSG is labeled by $(p_1, p_2, p_3)$ where $p_1, p_2, p_3 = 0, 1$. These three integers label the fractionalization of the translation $\sigma$ and $C_6$:

$$T_1 T_2 = T_2 T_1 (-1)^{p_1}, \quad \sigma^2 = (-1)^{p_2}, \quad C_6^2 = (-1)^{p_3}.$$

For each symmetry operation $X$, the corresponding projective symmetry operation is $G_X X$ where $G_X = e^{i\psi_X(r)}$ is a U(1) gauge transformation:

$$\varphi_{T_1}(x, y) = 0,$$

$$\varphi_{T_2}(x, y) = p_2 \pi x,$$

$$\varphi_{T_3}(x, y) = p_3 \pi + p_1 \pi xy,$$

$$\varphi_{C_6}(x, y) = p_1 \pi + p_1 \pi \left(\frac{xy + (y^2 - 1)}{2}\right). \quad (14)$$

where the coordinate of a site is $R = xa_1 + ya_2$. The transformation of crystal symmetries can be found in Appendix A.

For both Schwinger boson and Schwinger fermion, there are eight different Z2 spin liquids labeled by $(p_1, p_2, p_3)$. However, more constraints need to be added if we require the nearest-neighbor pairing to be nonzero. This is a reasonable requirement for a model with dominant nearest-neighbor antiferromagnetic coupling. It turns out there are only two Z2 spin liquids for both fermion and boson parton in the SO(6)-symmetric limit. In the following, we will introduce
the two PSG Ansätze for the Schwinger boson and Schwinger fermion, respectively. Then, we will connect the Schwinger fermion and Schwinger boson approaches and show that they describe the same $Z_2$ spin liquids in terms of $f$ particle and $e$ particle.

1. $Z_2$ spin liquid in Schwinger fermion parton

The only SO(6)-symmetric pairing is \( \Delta(\mathbf{R}) \sum_a \Psi_a(\mathbf{r}) \Psi_a(\mathbf{r} + \mathbf{R}) \) where \( a = 1, \ldots, 6 \) is the flavor index. For fermion we have \( \Delta(\mathbf{R}) = -\Delta(-\mathbf{R}) \). We require \( \Delta(\mathbf{R}) \neq 0 \) for nearest neighbor \( \mathbf{R} \). First, the reflection \( \sigma \) maps \( \mathbf{R} = (1,1) \) to itself. Under the PSG, \( \Delta(1,1) \rightarrow \Delta(1,1)e^{\epsilon(a_0(0,0)\tau_3(1,1))} \). To have \( \Delta(1,1) \neq 0 \), we need \( \varphi_\sigma(0,0) + \varphi_\sigma(1,1) = 0 \mod 2\pi \). This is equivalent to \( p_1 = p_2 \).

Second, \( \mathbf{R}_2 = (-1,0) \) is related to \( \mathbf{R}_1 = (1,0) \) by three \( C_6 \) rotations. Meanwhile, we have \( \Delta(-1,0) = -\Delta(1,0) \). Therefore, we have the following condition:

\[
3\varphi_{C_6}(0,0) + \varphi_{C_6}(1,1) + \varphi_{C_6}(0,1) + \varphi_{C_6}(-1,0) = \pi \mod 2\pi ,
\]

which requires \( p_3 = 1 - p_1 \mod 2 \). Because of the above two constraints, there are only two reasonable symmetric $Z_2$ spin liquids with SO(6) rotation symmetry. They are \( (0,0,1) \) and \( (1,1,0) \) phases. The first is a zero-flux phase while the second is a \( \pi \)-flux phase.

Next, we show that \( p_1 = 1 \) forbids nearest-neighbor hopping. Consider the hopping \( t(\mathbf{R}) \sum_a \Psi_a(\mathbf{r}) \Psi_a(\mathbf{r} + \mathbf{R}) \). \( \mathbf{R}_1 = (0,1) \) and \( \mathbf{R}_2 = (1,0) \) are related by \( \sigma \) or \( C_6 \). To have nonzero nearest-neighbor hopping, we need to have

\[
-\varphi_\sigma(0,1) + \varphi_\sigma(0,0) = -\varphi_{C_6}(1,1) - \varphi_{C_6}(0,1) + 2\varphi_{C_6}(0,0) \mod 2\pi
\]

which fixes \( p_1 = 0 \). As a result, the \( \pi \)-flux phase needs to have zero nearest-neighbor hopping.

2. $Z_2$ spin liquid in Schwinger boson parton

For six-flavor bosons, the pairing is also \( \Delta(\mathbf{R}) \sum_a \Psi_a(\mathbf{r}) \Psi_a(\mathbf{r} + \mathbf{R}) \) for each bond \( \mathbf{R} \). We have \( \Delta(\mathbf{R}) = -\Delta(-\mathbf{R}) \). Similar to the fermion case, the reflection \( \sigma \) fixes \( p_1 = p_2 \). The \( C_6 \) relates \( \mathbf{R}_1 = (1,0) \) to \( \mathbf{R}_2 = (-1,0) \) and fixes \( p_3 = p_1 \). There are also two symmetric spin liquids satisfying the following constraint: the zero-flux phase \( (0,0,0) \) and the \( \pi \)-flux phase \( (1,1,1) \). Again, the \( \pi \)-flux phase can not have nonzero nearest-neighbor hopping.

3. Equivalence between Schwinger boson and Schwinger fermion descriptions

We have found two symmetric $Z_2$ spin liquids from both Schwinger boson and Schwinger fermion construction. In this section we show that the Schwinger fermion descriptions are equivalent to the Schwinger boson approach.

In the Schwinger boson approach, we have the PSG for the bosonic $e$ particle. In the Schwinger fermion parton theory, we have the PSG for the fermionic $f = ev$. Here, $v$ denotes the vison or $m$ particle. The PSG of $f$ particle can be derived from the composition of the PSG of the $e$ and $m$ particles (with possible twisting factor) [43–45]. There is one $e$ particle per unit cell and the vison $v$ always sees the $e$ particle as an effective $\pi$ flux. Thus, the vison always has the PSG $T_1 T_2 = -\bar{T}_1 \bar{T}_2$ and $C_6^f = -1$. It has been shown that $\sigma^2 = -1$ is anomalous for the vison when there is a U(1) spin rotation symmetry. Vison must have $\sigma^2 = 1$ [46] in our problem. For the fractionalization of $X = T_1 T_2 (T_1 T_2)^{-1}$, $\sigma^2$, $C_6$, the PSG of vison \((-1)^1\) can be uniquely determined as $P^v = (-1,0,-1)$. We can then get PSG of $f$ from the PSG of $e$ particle by $(-1)^1 = (-1)^{\bar{X}} \bar{F} = a (\sigma^2 - 1) = 1 \bar{F}$, where $\bar{X} = 1$, $\bar{F}$ is a twist factor. It has been shown that $\epsilon(e) = 1$ and $\rho(\%2\) = $e(C_6^f) = -1$ [44,45]. We can then map PSG of $e$ particle $P^e = (p_1^e, p_2^e, p_3^e)$ to $P^v = (p_1^v, p_2^v, p_3^v)$ by the equation

\[
p_1^v = p_2^e + 1, \quad p_2^v = p_2^e + 1, \quad p_3^v = p_3^e.
\]

From the above relation we can see that both Schwinger boson theory and Schwinger fermion theory are describing two symmetric $Z_2$ spin liquids: I. $P^e = (0,0,0)$ and $P^v = (1,1,0)$. II. $P^b = (1,1,1)$ and $P^f = (0,0,1)$.

In summary, we find two symmetric $Z_2$ spin liquid, shown in Table II. Each of them can be described using either Schwinger boson or Schwinger fermion mean field Ansatz. Details about the Ansatz and the dispersion can be found in Appendix C.

V. PSEUDOGAP METALS AT $\nu_T = 2 - x$

After discussing the Mott insulator, we turn to possible metallic phases upon doping the Mott insulator. Especially, we show that pseudogap metals with small Fermi surfaces can naturally emerge upon doping the Mott insulator at $\nu_T = 2$. The Mott insulating phase at $\nu_T = 2$ is sensitive to the onsite intervalley spin-spin coupling $J_H$. A nonzero $J_H$ splits the SO(6) symmetry down to $1 \oplus 2 \oplus 3$. When $J_H > 0$ and its magnitude is much larger than $J$, it is obvious that the ground state is a featureless Mott insulator with one valley triplet, spin singlet at each site. When $J_H < 0$, with a large magnitude, the low energy is dominated by one SO(3) vector at each site. Therefore, we have an effective spin-one model on triangular lattice and the ground state is the 120° Neel order. For the intermediate region with $J_H = 0$, valence bond solid (VBS) or resonant valence bond (RVB) may also be possible.

In the remaining part we discuss possible metallic phases upon doping from the featureless Mott insulator and the VBS/RVB phase. The physics of doping the Neel order is very hard and we leave it to future work.

A. $J_H > 0$: Symmetric and featureless pseudogap metal

In the simplest case, let us assume $J_H > 0$ and is much larger than $J$. In this case, the Mott insulator has one
intervallley singlet at each site. When we dope the system to the filling $\nu_T = 2 - x$, there are $x$ singlons. One natural state is that these singlons move coherently and form four Fermi surfaces, each of which has area $A_{FS} = -\frac{1}{2}$. The remaining particles are still gapped out by singlet formation. Obviously, this is a pseudogap metal with only a small Fermi surface. The Hall number is opposite to the free-fermion case and is proportional to $x$. This is quite similar to the phenomenology of cuprates when superconductivity is suppressed by strong magnetic field. This pseudogap metal is a symmetric Fermi liquid. Although the picture is very simple, this state is definitely beyond the conventional scenario with density wave order. The existence of this simple example is a proof that electrons can be gapped out from the Fermi sea without invoking any symmetry-breaking order.

Although we can not describe this featureless pseudogap phase with the conventional mean field theory, we find that the essential physics can be easily captured by a slave-boson mean field theory. When we remove one electron from $\nu_T = 2$, we remove one doublon and create one singlon, therefore, we use the following partron representation:

$$c_x(x) = \sum_{\beta \neq \alpha} \Phi_{\alpha \beta}(x) f_\beta(x),$$

where $\alpha, \beta = 1, 2, 3, 4$ is the flavor index. $\Phi_{\alpha \beta}(x) = -\Phi_{\beta \alpha}(x)$ is an antisymmetric slave-boson field, which has been used before in Eq. (9). $f_\beta(x)$ creates a singlon with flavor $\beta$. The above partron construction has a $U(1)$ redundancy:

$$\Phi_{\alpha \beta}(x) \rightarrow \Phi_{\alpha \beta}(x)e^{i\phi(x)}, \quad f_\beta(x) \rightarrow f_\beta(x)e^{i\phi(x)}$$

with the constraint $n_f(x) + n_b(x) = 1$.

When $J_H = 0$, these six $\Phi_{\alpha \beta}$ fields can form a SO(6) vector in the basis defined in Eq. (9). In the following, we use the SO(6) basis $b_a(x)$ with $a = 1, 2, \ldots, 6$:

$$
\begin{align*}
 b_1 &= \frac{i}{\sqrt{2}}(-\Phi_{12} + \Phi_{34}), \\
 b_2 &= \frac{1}{\sqrt{2}}(-\Phi_{12} + \Phi_{34}), \\
 b_3 &= \frac{i}{\sqrt{2}}(-\Phi_{14} + \Phi_{23}), \\
 b_4 &= \frac{1}{\sqrt{2}}(-\Phi_{14} + \Phi_{23}), \\
 b_5 &= \frac{1}{\sqrt{2}}(\Phi_{13} - \Phi_{24}), \\
 b_6 &= -\frac{i}{\sqrt{2}}(\Phi_{13} - \Phi_{24}).
\end{align*}
$$

We can substitute Eq. (20) to the $t$-$J$ model in Eq. (8) and decouple it in the form of mean field theory.

$$H_M = H_b + H_f,$$

$$H_b = -b_\nu \sum_{\langle ij \rangle} b_{a,i}^\dagger b_{a,j} + \text{H.c.} - \mu \sum_i b_{a,i}^\dagger b_{a,i},$$

$$H_f = -t_f \sum_{\langle ij \rangle} f_{a,i}^\dagger f_{a,j} + \text{H.c.} - \mu_f \sum_i f_{a,i}^\dagger f_{a,i}. $$

When we add a $J_H > 0$, the degeneracy of the six-flavor bosons is lifted and the one corresponding to the intervallley singlet is favored. This is $b_1 = \frac{1}{\sqrt{2}}(-\Phi_{14} + \Phi_{23})$ defined in Eq. (20). Therefore, we consider the Ansatz with $(b_3(x)) \neq 0$. After the condensation of $b_3$, the internal U(1) gauge field is Higgsed and $f$ can be identified as a local hole operator $c^\dagger$. The density of fermion $f$ is $n_f = x$. We have four Fermi surfaces with Fermi surface area $A_{FS} = -\frac{1}{2}$.

To further prove the phase is a Fermi liquid, we can try to calculate the single Green function. With simple algebras, we can easily get

$${G}^c_{\alpha_1, \alpha_2}(x, t; y, t') = \langle c_{\alpha_1}(x, t)c_{\alpha_2}(y, t') \rangle$$

$$= \sum_{\beta_1 \neq \alpha_1} \sum_{\beta_2 \neq \alpha_2} \langle i \Phi_{\alpha_1 \beta_1}(x, t)f_{\beta_1}(x, t)f_{\beta_2}^\dagger(y, t') \rangle$$

$$= \sum_{\beta \neq \alpha_1, \alpha_2} \langle i \Phi_{\alpha_1 \beta}(x, t)f_{\alpha_2 \beta}(y, t') \rangle {G}^c_{\alpha_2}(x, t; y, t').$$

Using the fact that $\langle \Phi_{\alpha_1 \beta} \rangle = -(\Phi_{23}) = \frac{1}{\sqrt{2}}(b_4)$ while other components of $\Phi_{\alpha \beta}$ are zero, we can easily get

$${G}^c_{11}(x, t; y, t') = \frac{1}{2} \langle b \rangle^2 {G}^f_{14}(x, t; y, t'),$$

$${G}^c_{22}(x, t; y, t') = \frac{1}{2} \langle b \rangle^2 {G}^f_{22}(x, t; y, t'),$$

$${G}^c_{33}(x, t; y, t') = \frac{1}{2} \langle b \rangle^2 {G}^f_{22}(x, t; y, t'),$$

$${G}^c_{44}(x, t; y, t') = \frac{1}{2} \langle b \rangle^2 {G}^f_{22}(x, t; y, t').$$

These equations also mean that the $f$ operator should be identified as a physical hole operator.

In summary, in the limit with a large anti-intervallley Hund’s coupling, a natural state in the underdoped regime is a symmetric and featureless Fermi liquid with small Fermi surfaces. Such a state has Hall number $\eta_H = -x$ for $\nu_T = 2 - x$, in contrast to the free-fermion case with $\eta_H = 2 - x$. This simple state offers a simple example to partially gap out free-fermion Fermi surfaces by symmetric singlet formation, instead of the more familiar density wave order.

**B. $J_H = 0$: Orthogonal metal with small Fermi surfaces**

Next, we turn to the case with $J_H = 0$. In this U(4)-symmetric point, Luttinger theorem requires $A_{FS} = \frac{\nu_T}{4}$ for a symmetric and featureless phase. However, we will argue that an exotic symmetric pseudogap metal may be possible when doping away from the $\nu_T = 2$ Mott insulator in the $U \gg t$ limit. We will generalize the conventional RVB theory [37] to the type II $t$-$J$ model close to $\nu_T = 2$. As in the familiar RVB theory, we assume the undoped state is a $Z_2$ spin liquid.

We still use the partron construction in Eq. (18). We have $n_f = x$ and $n_b = 1 - x$. In the undoped Mott insulator, there are two $Z_2$ spin liquids as we proposed before. For simplicity, we just use the zero-flux Ansatz from the Schwinger boson method. Basically, the Schwinger boson $b$ is in a paired superfluid phase. Then, we dope the system, $f$ can form four Fermi surfaces with area $A_{FS} = -\frac{1}{2}$ as in the featureless pseudogap metal in the previous subsection. In this mean field Ansatz, $(b_b f) \neq 0$ Higgs the internal U(1) gauge field down to $Z_2$. As argued in Ref. [34], in this case the physical charge is carried by fermion $f$. In another way, we can use Ioffe-Larkin rule for
physical resistivity \cite{47}: \( \rho_c = \rho_0 + \rho_f \). Because the boson \( b \) is in a paired superfluid phase, \( \rho_0 = 0 \), therefore, \( \rho_c = \rho_f \). We conclude that the transport property of this phase is exactly the same as a Fermi liquid with small Fermi surfaces. Obviously, we will also expect Hall number \( n_H = -x \) as in the featureless pseudogap metal. The thermodynamic property, like specific heat or spin susceptibility, should still be the same as the featureless pseudogap metal. Therefore, we still view this phase as a “pseudogap metal” because the number of carriers is much smaller than the conventional Fermi liquid.

Next, we will show that this pseudogap metal is a non-Fermi-liquid (NFL) instead of a Fermi liquid in terms of single-electron Green function. Following the same analysis as in the previous subsection, we can get \( G^\tau(x, y; t, t') \propto \langle b^\dagger(x, t)b(y, t') \rangle G^\tau(x, y; t, t') \), where we have suppressed the flavor index for simplicity. Because the Schwinger boson \( b \) is in a paired-superfluid phase, a single-particle Green function \( \langle b^\dagger(x, t)b(y, t') \rangle \) should be an exponential decay. As a result, a single Green function for the physical electron \( G^\tau(x, y; t, t') \) should also be an exponential decay. As a consequence, ARPES or STM measurement can not detect any coherent quasiparticle for this pseudogap metal. The charge carrier in this exotic metal is not the physical electron. We will follow the notation of Ref. \cite{34} and dub it as “orthogonal metal.”

In summary, we have shown that a featureless pseudogap metal or an orthogonal metal with small Fermi surfaces \( A_{FS} = -\frac{t}{J} \) can naturally emerge at filling \( \nu_F = 2 - x \) for large positive \( J_H \) or small \( J_H \). For a negative and large \( J_H \), we know that the \( \nu_F = 2 \) Mott insulator is in the 120° Neel order for the low-energy spin-one model. Doping such a Neel order may show a new metallic or superconducting phase beyond the analysis here, which we leave to future work.

VI. DECONFINED METAL BETWEEN PSEUDOGAP METAL AND CONVENTIONAL FERMI LIQUID

At the large \( U \gg t \) limit, we have argued that a pseudogap metal with small Fermi surfaces is likely at small doping away from \( \nu_F = 2 \). Then, a natural question is how this small Fermi surface pseudogap metal evolves to the conventional Fermi liquid with large Fermi surfaces when increasing \( J_H \) or the doping \( x \). We try to provide one possible scenario in this section.

For simplicity, we work in the case with \( J_H = 0 \). We have already presented a description of the orthogonal metal with small Fermi surfaces. Next, we need to understand how to describe the conventional Fermi liquid with large Fermi surfaces. At large \( J_H \), this is a trivial problem. At the large \( U \gg t \) with large doping \( x \), we still expect a conventional Fermi liquid, which can not be simply understood as in the free-fermion case because of the constraint \( P_2 \) in Eq. (8). In the familiar spin-\( \frac{1}{2} \) case or in the filling \( \nu_F = 1 - x \) of the U(4) model, the constraint in Eq. (7) can be respected in the slave-boson description: \( c_a(x) = b^\dagger(x)f_a(x) \). Then, the conventional Fermi liquid just corresponds to the Ansatz with \( \langle b(x) \rangle \neq 0 \). In contrast, in the case \( \nu_F = 2 - x \), the Hilbert space consists of singlon and doublon. Neither of them can simply condense without breaking spin rotation symmetry. Meanwhile, the density of a singlon is \( x \) while the number of a doublon is \( 1 - x \). Therefore, to have the conventional Fermi liquid with Hall number \( \eta_H = 2 - x \), we need both singlons and doublons to be absorbed to form the large Fermi surface with area \( a_{FS} = \frac{2 - x}{2} \). In the following, we will show that a large Fermi surface state can be generated from “Kondo resonance” similar to heavy-fermion systems.

To impose the constraint \( P_2 \) in Eq. (8), we still use the parton construction in Eq. (18). With this parton construction, we can define spin operators for the doublon site using the slave boson \( b_n \) (linear transformation of \( \Phi_{a\mu} \)) and the spin operators for the singlon site using the fermion \( f \).

The spin operator for the doublon site is

\[
S^{\mu
u}_{d}(x) = 2i[b^\dagger_{a}(x)b_{a}(x) - b^\dagger_{b}(x)b_{b}(x)],
\]

where \( a, b = 1, 2, \ldots, 6 \). \( S^{\mu\nu}_{ab} \) is the generator of the SO(6) group. It has a one-to-one correspondence to the SU(4) spin operators as defined in Table I.

The spin operator for the singlon site is

\[
S^{\mu\nu}_{s}(x) = f^\dagger_{a}(x)\tau^\mu_x\tau^\nu_y f_{a}(x),
\]

where \( \alpha, \beta = 1, 2, 3, 4 \). \( \tau^\mu_x \) with \( \mu = 0, x, y, z \) except \( \mu = v = 0 \). With this six-flavor slave-boson parton construction, the \( t, J \) model defined in Eq. (8) looks like an exchange term between the singlon \( f \) and the doublon \( b^\dagger b f \). Here, we suppressed the flavor index because generically it looks quite complicated and involves many different terms. This term can be decoupled to the mean field Ansatz in Eq. (21). The J term in this case involves terms like \( S_{b\nu}S_{a\nu}, S_{f\nu}S_{f\nu}, \) and \( S_{b\nu}S_{f\mu} \). At small doping \( x \), we have \( n_b = 1 - x \) and \( n_f = x \). In this case, we can view the doublon site as a SO(6) spin and the fermion \( f \) couples to the SO(6) moment through the term \( S_{b\nu}S_{f\mu} \), which resembles a Kondo coupling in the heavy-fermion problem. Then, a large Fermi surface may be generated through “Kondo resonance.”

The essential point of Kondo resonance is to absorb the SO(6) spin to form a large Fermi surface with area \( A_{FS} = \frac{2 - x}{4} \). To do that, we need to split a doublon to two fermions first. Therefore, we do a further parton construction on top of Eq. (18):

\[
\Phi_{a\mu} = \frac{1}{2}[\psi_{a}(x)\psi_{\mu}(x) - \psi_{\mu}(x)\psi_{a}(x)].
\]

In other words, the original electron operator is now written

\[
c_{a}(x) = \sum_{\beta \neq a} \psi_{a}(x)\psi_{\beta}(x)f^\dagger_{\beta}(x)
\]

with the constraint \( \frac{1}{4}n_{\psi} + n_{f} = 1 \). Still, there is a U(1) gauge redundancy

\[
f_{\mu}(x) \rightarrow f_{\mu}(x)e^{i\psi_{\mu}(x)}, \quad \psi_{a}(x) \rightarrow \phi^{\dagger}_{a}(x).
\]
the Fermi surfaces formed by $\psi$ and $f$ couple to an internal U(1) gauge field $a$. We can condense either $\psi \bar{\psi} V$ or $\psi \bar{\psi} V 2$ to get featureless pseudogap metal or orthogonal pseudogap metal, where $V$ is the vison annihilation operator.

The pairing term will completely Higgs the U(1) gauge field $a$. However, the $Z_2$ gauge field still survives and decouples with the remaining Fermi surfaces formed by $f$. This is actually a FL* phase with Fermi liquid coexisted with $Z_2$ gauge field. To avoid such an exotic state and get the featureless pseudogap metal, we should condense $\langle \psi \bar{\psi} V \rangle \neq 0$ where $V$ is the vison of the $Z_2$ gauge field. In this way, the $Z_2$ gauge field also gets confined and we get exactly the featureless pseudogap metal. In the SU(4)-symmetric point, the orthogonal pseudogap metal may be favored. We can reach it through $\langle \psi \bar{\psi} V \rangle \neq 0$. In the saddle point, the internal gauge field flux $b$ is locked to the external magnetic field: $b = aB$ with $\alpha = \frac{4\chi_f}{\chi_4 + 4\chi_f}$. Here, $\chi_4$ and $\chi_f$ are the diamagnetism susceptibility in the Gaussian approximation. Generically, we expect $\alpha$ is an order one number smaller than one. Using $\chi \sim \frac{1}{m}$ for a Fermi surface, we have $\alpha = \frac{4m_0}{4m_0 + m_f}$. Because of the locking, $\psi$ sees an effective field $aB$ while $f$ sees an effective field $-(1 - \alpha)B$. Then, in principle, one should see quantum oscillations corresponding to the Fermi surfaces area for both $\psi$ and $f$ with frequency renormalized by factor $\alpha$ and $1 - \alpha$.

Next, we discuss the Hall number of this deconfined metal. The constraint $\frac{1}{2}n_\psi + n_f = 1$ implies that $J_\psi = J_f$, where $J_\psi = J$ is defined as variation of $\ell_\psi$ while $J_f$ is defined as variation of $a$. In the Gaussian approximation, we have the result

$$
E_x = \frac{n_f e B^2}{n_\psi e f} f^y,
$$

and

$$
E_x = \frac{1 - \alpha}{n_f e} B J_f.
$$

where we have used the result $\rho_{xy} = \frac{\kappa}{nQ}$ for a Fermi surface with charge $Q$ and density $n$.

Then, it is easy to get

$$
\frac{1}{\eta_H} = \left( \alpha \frac{2\alpha}{n_\psi e} - 1 \right) \frac{n_f e}{n_f e}.
$$

or

$$
\frac{1}{\eta_H} = \frac{\alpha}{1 - x} \left( 1 - \alpha \right)^{-1}.
$$

Note that, generically, $\eta_H$ is not related to the density of charge carriers. At the limit $x \ll 1$ and $\alpha \ll 1$, we have $\eta_H \approx \frac{\alpha}{1 - \alpha}$. $\eta_H$ diverges when $\alpha$ increases to $1 - x$. Therefore, the Hall number can be arbitrary inside the deconfined metal, depending on the value of $\alpha$.

Once the system is in the FL phase, $\langle \psi^2 f \rangle$ locks $a = 2A$. In this case, $\psi$ forms an electron pocket while $f$ can be viewed as a charged $\alpha$ quasihole.
as a hole pocket. Deep inside the FL phase, the two Fermi
surfaces merge together to form a large electron Fermi surface
and \( \eta_H = 2 - x \).

In the above we have described one scenario for evo-
lution from pseudogap metals to conventional Fermi liquid
by increasing doping or bandwidth. In this simple scenario,
there is an intermediate deconfined metal phase. The physics
of the pseudogap metal we described is kind of similar to the
"symmetric mass generation" proposed in Ref. [48] for
Dirac fermions. In that simple, case Ref. [48] constructed a
decomposed critical point between an insulator and a Dirac
semimetal. It is not clear whether a direct transition between
the pseudogap metal and the conventional Fermi liquid can
exist or not in our case. We hope to study this in the future.

VII. U(1) SPINON FERMI-SURFACE STATE AND Z4 SPIN
LIQUID AT \( v_T = 1 \)

At \( v_T = 1 \), the intervalley Hund’s term \( J_H \) vanishes af-
ter projection to the Hilbert space without double occu-
pancy. Therefore, the spin rotation symmetry is SU(4)/Z4 or
U(1)_{valley} \times SO(3)_x \times SO(3)_y. We will show that there is no
symmetric gapped Z2 spin liquid when spin rotation symmetry
is both SU(4)/Z4 and U(1)_{valley} \times SO(3)_x \times SO(3)_y. Within
the Abrikosov fermion parton construction, the only symmet-
ric spin-liquid state is a U(1) spin liquid with spinon Fermi
surface, which can be reached from the Fermi-liquid phase
through a continuous transition. A symmetric Z4 spin liquid
is also possible but beyond mean field description.

A. Absence of gapped symmetric Z2 spin liquid

There is a general argument to rule out gapped Z2 spin
liquid with full spin rotation symmetry. Because there is
only one fundamental representation within each unit cell,
in a spin rotation invariant Z2 spin liquid, the spinon needs
to transform as \( \frac{\tau}{2}, 0 \) and \( (0, \frac{1}{2}) \) under SU(2)_x \times SU(2)_y.
Basically, we have \( e_{\tau \pi} \) carries valley + and \( e_{-\pi} \) carries
valley −. A bound state formed by \( e_{\tau \pi} e_{\pi \tau} \) has dimension 4
and transforms as \( \frac{1}{2}, \frac{1}{2} \) under SU(2)_x \times SU(2)_y. Under 2π
rotation of \( S_z \) for either valley, it acquires a global −1 phase.
Therefore, the bound state is in the projective representa-
tion of U(1)_{valley} \times SO(3)_x \times SO(3)_y. However, in a gapped Z2 spin
liquid, \( e_{\tau \pi} \) is created by a local operator and should be in a
linear representation. The contradiction implies that a gapped
symmetric Z2 spin liquid is not possible.

B. U(1) spin liquid in Abrikosov fermion parton construction

A U(1) spin liquid is possible and can be constructed in
the standard Abrikosov fermion parton theory. For the
current problem, Schwinger boson parton theory is not very useful
because there is no symmetric paired condensation phase of
the four-flavor Schwinger bosons. Therefore, we restrict to
Abrikosov fermion parton theory. At each site, we have \( f_{ab} \)
in the fundamental representation of SU(4) with the constraint
\[ \sum_a f_{ab} f_{ba} = 1. \] Unlike the spin-\( \frac{1}{2} \) case, there is only a U(1)
gauge redundancy.

Apparently, there can not be pairing term which preserves
the spin rotation symmetry. This is another manifestation that
symmetric Z2 spin liquid is not possible. In the following, we
classify all possible symmetric U(1) spin-liquid states.

The projective symmetric group (PSG) for U(1) spin liquid
is classified in Appendix B. There are only two possible PSG,
which are labeled by the projective translation symmetry:
\( T_1 T_2 = T_2 T_1 e^{i \Phi_\sigma} \). It turns out only \( \Phi_T = 0 \) and \( \Phi_T = \pi \) are
compatible with the reflection symmetry \( \sigma \). Once \( \Phi_T = \pi \), the
symmetry realizations of \( \sigma \) and \( C_6 \) are also fixed. Note that
\( C_6^0 \) and \( \sigma^2 \) are meaningless in a U(1) spin liquid because
a global U(1) transformation can always be added in \( C_6 \) and
\( \sigma \). For each symmetry operation \( X \), the symmetry realization
is \( e^{i \Phi_\sigma (X)} X \). The following is a list of the PSG:

\[
\begin{align*}
\phi_T &= 0, \\
\phi_T &= p_1 \pi x, \\
\phi_T &= p_1 \pi y, \\
\phi_T &= p_1 \pi (x+y) \\
\phi_T &= p_1 \pi xy + \frac{1}{2} p_1 \pi (y-1) 
\end{align*}
\]

up to a constant phase. \( \Phi_T = p_1 \pi \) with \( p_1 = 0, 1 \). \( p_1 = 0 \)
and \( p_1 = 1 \) label the zero-flux phase and the \( \pi \)-flux phase.
However, in the \( \pi \)-flux phase the nearest-neighbor hopping
and the next-nearest-neighbor hopping are forbidden. This
\textit{Ansatz} is not energetically favorable. Therefore, we only
consider the zero-flux phase.

In the zero-flux phase, \( \phi_X = 0 \). Therefore, all of the sym-
metry operations are realized trivially. The phase is a U(1)
spin liquid with four Fermi surfaces, each at filling \( \frac{1}{4} \).
This spin-liquid phase can be reached from the Fermi-liquid side
through a continuous quantum phase transition. In principle,
the symmetric Z4 spin liquid is also possible. In the Abrikosov
fermion description, the fermion can form a charge-4e
singlet pairing: \( \langle \epsilon_{\alpha \beta \gamma \delta} f_\alpha f_\beta f_\gamma f_\delta \rangle \neq 0 \), resulting in a symmetric Z4 spin
liquid.

For the spin-valley model at \( v_T = 1 \), there is no symmetric
featureless Mott insulator and magnetic order may be sup-
pressed because of the frustration of triangular lattice and
large quantum fluctuation space. The most likely competing
ordered state is a plaquette order with four sites forming a
SU(4) singlet. If such a plaquette order is melted, we can get
a quantum spin-liquid phase. In this case, our PSG analysis
suggests a U(1) spin liquid with spinon Fermi surface or a Z4
spin liquid.

A superconductor has been reported at small doping away
from the \( v_T = 1 \) Mott insulator [10]. For both the Z4 spin
liquid and the plaquette order, the Mott insulator is a SU(4)
singlet. Therefore, upon doping, the most likely supercondu-
tor has charge-4e pairing. A charge-4e superconductor will
be killed by in-plane Zeeman field, which is consistent with
the experiment [10]. In contrast, a conventional charge-2e
pairing lives on a SU(4) manifold because valley triplet, spin
singlet pairing is degenerate with the valley singlet, spin triplet
pairing. A Zeeman field will select the spin triplet pairing and
there is no reason to expect the \( T_\sigma \) to be suppressed by Zeeman
field. Given the experimental phenomenology and the possible
SU(4)-symmetric Mott insulator nearby, the possibility that
the observed superconductor is charge-4e paired should be
taken seriously. We leave a detailed analysis of charge-4e
superconductor to future work.
VIII. CONCLUSION
In this paper, we study possible interesting phases in a spin-valley Hubbard model on triangular moiré superlattice. We show that pseudogap metals with small Fermi surfaces can naturally emerge by doping the νr = 2 Mott insulator. In the moiré materials, it is also easy to study the possible transition between the pseudogap metals and the conventional Fermi liquid by tuning either doping or displacement field. We propose one possible route through an intermediate deconfined metallic phase. We also comment on possible spin liquids at νr = 1 and charge-4e superconductor nearby. Our proposals can be easily tested in ABC trilayer graphene aligned with hBN and in twisted transition metal dichalcogenide homobilayers. The existence of two distinct symmetric Fermi liquids from symmetry analysis is also true for the graphene moiré systems with topological bands. In the future, it is interesting to study whether a similar symmetric Fermi liquid with small Fermi surfaces can naturally exist in the topological case.

We thank T. Senthil for very helpful discussions. This work was supported by US Department of Energy Grant No. DE-SC000873.

APPENDIX A: CRYSTAL SYMMETRY OF TRIANGULAR LATTICE

We define r = xa1 + a2. The lattice symmetries are

\[ T_1 : (x, y) \to (x + 1, y), \]
\[ T_2 : (x, y) \to (x, y + 1), \]
\[ \sigma : (x, y) \to (y, x), \]
\[ C_6 : (x, y) \to (x - y, x). \]  

The following algebraic constraints are useful:

\[ T_2 T_1 = T_1 T_2, \]
\[ T_1 C_6 = C_6 T_1, \]
\[ T_2 C_6 = C_6 T_2, \]
\[ T_1 \sigma = \sigma T_2, \]
\[ T_2 \sigma = \sigma T_1, \]
\[ C_6 \sigma = \sigma C_6, \]
\[ C_6^2 = 1, \]
\[ \sigma^2 = 1, \]
\[ C_6 \sigma = \sigma C_6^3. \]  

APPENDIX B: PROJECTIVE SYMMETRY GROUP CLASSIFICATION FOR U(1) SPIN LIQUID

At νr = 1, we can use the Abrikosov fermion in the SU(4) fundamental representation. At νr = 2, we can have U(1) spin liquid described by a six-flavor Schwinger fermion. In this Appendix we classify all symmetric U(1) spin-liquid states within the fermion parton theory for both νr = 1 and 2. First, invariant gauge group (IGG) is \( \{ e^{i\theta} \} \) where \( \theta \in [0, 2\pi) \) is a constant phase. For each symmetry operation \( X \), we can parametrize the gauge transformation as \( G_X(r) = e^{i\phi_X}(r) \). Under gauge transformation \( G(x) = e^{i\phi(x)} \), the \( G_X \) should be replaced by \( GG_X XG^{-1}X^{-1} \). Correspondingly we have

\[ \phi_X(r) \to \phi_C(r) + \phi_X(r) - \phi_C(X^{-1}r). \]  

Next, we need to fix the gauge. Following Wen and Fa Wang et al. [42], we fix \( \phi_T(r) = 0 \). This can be done by solving the equations

\[ \phi_C(x, y) + \phi_X(x, y) - \phi_C(x - 1, y) = 0. \]  

These two equations fix dependence of \( \phi_x(x, y) \) on \( x \). If \( G(0, y) \) is fixed, then \( G(x, y) \) is fixed. Now, we only have the gauge freedom \( G(0, y) \). Then, we can use \( T_1 T_2 = T_2 T_1 \) to fix \( G_T \). Using \( T_1^{-1} T_2 T_1 T_2^{-1} = I \), we have

\[ \phi_T(x, y) = \phi_T(0, y) + \Phi_T x. \]  

where \( \Phi \in [0, 2\pi) \) is a position-independent constant. We can use the remaining gauge freedom \( G(0, y) \) to make \( \phi_T(0, y) = 0 \). Because IGG is U(1), a constant phase in \( \phi \) does not matter. A nonzero \( \Phi \) means a projective translation symmetry: \( T_1 T_2 = T_2 T_1 e^{i\Phi} \). We need to fix \( \Phi = 0 \), where \( p, q \) are integers.

Next, we need to find PSG for \( \sigma \) and \( C_6 \). First, we need to point out the remaining gauge freedom we can use. The first one is \( G_1 : \phi_1 = \text{const} \). The second one is \( G_2 : \phi_2(x, y) = \theta x \). This will change \( \phi_T \). However, it belongs to the IGG and does not matter. The third one is \( G_3 : \phi_3(x, y) = \theta y \). This gauge of freedom can be used to eliminate redundant parameters later.

Finally, we get \( \phi_{\sigma}(x, y) = \Phi_T x y + \text{const} \). From \( T_1^{-1} \sigma T_2 \sigma^{-1} = I \) and \( T_1^{-1} \sigma T_1 \sigma^{-1} = I \) we have

\[ \phi_{\sigma}(x + 1, y) - \phi_{\sigma}(x, y) = -\Phi_T y + \phi_2', \]
\[ \phi_{\sigma}(x, y + 1) - \phi_{\sigma}(x, y) = \Phi_T x + \phi_3'. \]  

where \( \phi_2', \phi_3' \) are constant phases.

From these equations we can get \( \phi_{\sigma}(X, Y) = \phi_{\sigma}(0, 0) + \phi_2 X + \phi_3 Y + \Phi_T X Y \text{mod} 2\pi = \phi_{\sigma}(0, 0) + \phi_2 X + \phi_3 Y - \Phi_T X Y \text{mod} 2\pi \). To have solution, we need to fix \( \Phi_T = 0, \pi \). Therefore, a general flux \( \Phi \) is not compatible with the reflection symmetry. In the following, we can use the notation \( \Phi_T = p_1 \pi \). A general solution is

\[ \phi_{\sigma}(x, y) = \phi_{\sigma}(0, 0) + p_1 \pi x y + \phi_2' x + \phi_3' y. \]  

From \( \sigma^2 = I \) we have

\[ \phi_{\sigma}(x, y) + \phi_{\sigma}(y, x) = 2\phi_{\sigma}(0, 0), \]  

which fixes \( \phi_2' = -\phi_3' \text{mod} 2\pi \).

Now, we can use the gauge freedom \( G_2 = e^{i\phi_2 x} \) to reduce the parameters. \( \phi_{\sigma}(x, y) \) changes to

\[ \phi_{\sigma}(x, y) \to \phi_{\sigma}(x, y) + \theta_2(x - y) \]
\[ \to \phi_{\sigma}(0, 0) + p_1 \pi x y + (\phi_2' + \theta_2)(x - y). \]  

We can always choose \( \theta_2 = -\phi_2' \). Finally, we have the PSG for \( \sigma' \):

\[ \phi_{\sigma'}(x, y) = p_1 \pi x y + \text{const}. \]
The next task is $C_6$. We can still use $G_1$ and $G_2G_3$, which do not change $G_1$, $G_2$, $G_3$ up to a constant phase. Using $T_1^{-1}C_6 T_2^{-1}C_6^{-1} = I$ and $T_2^{-1}C_6 T_1 C_6^{-1} = I$, we can get
\[
\varphi_{C_6}(x+1,y) - \varphi_{C_6}(x,y) = \phi_4 + p_1 \pi y,
\]
where $\phi_4$, $\phi_5$ are constant U(1) phases. A general solution is
\[
\varphi_{C_6}(x,y) = \varphi_{C_6}(0,0) + p_1 \pi x y - \frac{1}{2} p_1 y( y -1) \pi + \phi_4 x + \phi_5 y.
\] (B10)

$C_6 \sigma C_6 \sigma$ further impose the constraint

\[
\varphi_{C_6}(x,y) = \varphi_{C_6}(0,0) + p_1 \pi x y - \frac{1}{2} p_1 y( y -1) \pi + \phi_4 x + \phi_5 y.
\] (B11)

which fixes $\phi_4' + 2 \phi_5' = 0 \mod 2 \pi$. $C_6' = I$ imposes the constraint $\phi_6' = 0 \mod 2 \pi$. Then, we can also fix $\phi_6' = p_3' \pi$ with $p_3' = 0,1$.

Under the gauge transformation $G'_3 = e^{ih_3(x+y)}$, the solution of $\varphi_{C_6}$ changes to
\[
\varphi_{C_6} \rightarrow \varphi_{C_6}(0,0) + p_1 \pi x y - \frac{1}{2} p_1 y( y -1) \pi + (p_3' \pi - \theta_3)y + 2 \theta_3 x.
\] (B12)

Choosing $\theta_3 = p_3' \pi$, $\varphi_{C_6}$ can always be reduced to
\[
\varphi_{C_6} = p_1 \pi x y + \frac{1}{2} p_1 y( y -1) \pi
\] (B13)
up to a constant phase.

\section*{APPENDIX C: MEAN FIELD OF Z2 SPIN LIQUID AT $v_\tau = 2$}

In this Appendix we analyze the mean field Ansatz for SO(6)-symmetric Hamiltonian with only nearest-neighbor coupling $J$ at $v_\tau = 2$ based on the Schwinger fermion and the Schwinger boson parton theories. We focus on the two symmetric $Z_2$ spin liquids.

\subsection*{1. Type I $Z_2$ spin liquid}

The type I $Z_2$ spin liquid has PSG $P^b = (0,0,0)$ and $P^f = (1,1,0)$. The bosonic $e$ spinon has a trivial PSG while the $f$ particle is in a $\pi$-flux phase. We can get the dispersions of the $e$ particle and the $f$ particle from the Schwinger boson and the Schwinger fermion mean field theories, respectively.

\textbf{a. Mean field theory for the bosonic spinon}

The dispersion of the $e$ particle is described by the Schwinger boson mean field theory with zero-flux Ansatz. We have both nearest-neighbor hopping and pairing terms. Because all of the six bosons decouple with each other in the mean field level, we can work with a spinless boson $b$ at filling $n_b = \frac{1}{6}$ with the Hamiltonian

\[
H_b = \frac{1}{2} \sum_{(ij)} b_i^\dagger b_j - \Delta^e \sum_{(ij)} (b_i b_j + \text{H.c.}) - \mu \sum_{i} b_i^\dagger b_i
\] (C1)
or in momentum space
\[
H_b = \frac{1}{2} \sum_{k} (b^\dagger (k), b(-k)) \begin{pmatrix} \xi(k) & -\Delta^e (k) \\ -\Delta^e (k) & \xi(-k) \end{pmatrix} \begin{pmatrix} b(k) \\ b^\dagger(-k) \end{pmatrix} + \cdots
\] (C2)
where $\Delta(k) = \sum_{\mathbf{R}} \Delta e^{-\mathbf{k} \cdot \mathbf{R}}$.

Using the standard Bogoliubov transformation
\[
\alpha_{b_k} = \mu_k b_k + \nu_k b_k^\dagger
\] (C3)
with the constraint
\[
\mu^2 (k) - \nu^2 (k) = 1.
\] (C4)

The inverse transformation is
\[
b_k = \mu_k \alpha_{b_k} - \nu_k \alpha_{b_k}^\dagger.
\] (C5)
where we assumed $\mu_k = \mu_{-k}$ and $\nu_k = \nu_{-k}$.

The solution is
\[
\mu_k^2 = \frac{1}{2} \left( \frac{\xi(k)}{E_k} + 1 \right),
\]
\[
\nu_k^2 = \frac{1}{2} \left( \frac{\xi(k)}{E_k} - 1 \right)
\] (C6)
with the sign
\[
2 \mu_k \nu_k = - \frac{\Delta}{E_k}.
\] (C7)

The final dispersion is
\[
H = \frac{1}{2} \sum_{k} E_k (\alpha_k^\dagger \alpha_k + \alpha_{-k}^\dagger \alpha_{-k}) + E_0.
\] (C9)

At zero $T$, the expectation value is $\langle \alpha_k^\dagger \alpha_k \rangle = 0$, which leads to
\[
\langle b_k^\dagger b_k \rangle = \nu_k^2
\] (C10)
and
\[
\langle b_k b_{-k} \rangle = - \mu_k \nu_k = \frac{\Delta_k}{2E_k}.
\] (C11)

Finally, we get the self-consistent equation
\[
\frac{1}{N} \sum_k \nu_k^2 = \frac{1}{6},
\]
\[
t = 24 \left( 1 + \frac{1}{6} \right) J \frac{1}{N} \sum_k \nu_k^2 e^{i a_{1k}},
\]
\[
\Delta = 24 \left( 1 + \frac{1}{6} \right) J \frac{1}{N} \sum_k \frac{\Delta_k}{2E_k} e^{-k a_{1k}}.
\] (C12)

where $a_{1k} = (1,0)$ is one bond. The mean field energy is
\[
E_M = 28 J \sum_{(ij)} (b_i^\dagger b_j)^2 - (b_i b_j)^2).
\] (C13)

For total density $n_b = 0.5/6$, we find an Ansatz with $t = 0.795J$ and $\Delta = 3.644J$. Such an Ansatz has band bottom at the $\Gamma$ point. The mean field energy is $E_M = -0.03732 \times 42 J$. The critical density for condensation is around 1.45. The condensation of $e$ particle leads to a ferromagnetic state, which is apparently not physical for an antiferromagnetic spin model.
We need to fix the filling \( \langle k_1 \rangle = \frac{1}{2} \). The pairing \( \text{Ansatz} \) is \( \Delta_{ij} = -\Delta_{ji} \). The \( \pi \)-flux \( \text{Ansatz} \) has two inequivalent sublattices \( A \) and \( B \). In the momentum space, the dispersion is

\[
H(k) = \frac{1}{2} \sum_{k \in \text{sBZ}} \left( f^\dagger_A(k), f^\dagger_B(k), f_A(-k), f_B(-k) \right)
\]

\[
\times H(k) \left( f_A(k), f_B(k), f_A^\dagger(-k), f_B^\dagger(-k) \right),
\]

where \( \text{sBZ} \) is a smaller rectangular BZ with half area. \( H(k) \) is

\[
H(k) = \begin{pmatrix}
-\mu I & P(k) \\
P(k)^\dagger & \mu I
\end{pmatrix},
\]

where \( I \) is the identity matrix with \( 2 \times 2 \) dimension. \( P(k) \) is

\[
P(k) = 2i\Delta(\sin k_1\delta_+ + \sin k_2\sigma_x - \cos k_3\sigma_y),
\]

where \( k_1 = k \cdot a_2 = k_x, \ k_2 = k \cdot a_2 = -\frac{1}{2}k_x + \frac{\sqrt{5}}{2}k_y, \) and \( k_3 = k \cdot (a_1 + a_2) = \frac{1}{2}k_x + \frac{\sqrt{3}}{2}k_y \). The dispersion is

\[
E(k) = \sqrt{\mu^2 + 4\Delta^2(\sin^2 k_1 + \sin^2 k_2 + \cos^2 k_3)}.
\]

Self-consistently we find \( \Delta = 4.213J \) with mean field energy \( E_M = -0.0226 \times 42J \). \( \mu = -8.93J \).
The pairing term is odd under inversion. The direction of the arrow denotes the positive pairing. The self-consistent equations are

\[
\frac{1}{2} \sum_{k \in sBZ} \left( \frac{|\mu|}{E_k} - 1 \right) = \frac{1}{6},
\]

\[28J \sum_{k \in sBZ} \frac{4(\cos^2 k_1 + \cos^2 k_3 + \sin^2 k_2)}{12E_k} = \Delta. \quad (C23)\]

The sBZ is defined as \( k_x \in [-\pi, \pi] \) and \( k_y \in [-\frac{\pi}{\sqrt{3}}, \frac{\pi}{\sqrt{3}}] \). The solution is \( \Delta = 5.1095J \) with mean field energy \( E_{MF} = -0.0333 \times 42J \). The critical density for condensation is around 5.09, which is quite large.

The band minima of the dispersion are at the following four points: \( \mathbf{k}_1 = (\frac{\pi}{6}, \frac{\pi}{\sqrt{3}}), \mathbf{k}_2 = (\frac{5\pi}{6}, \frac{\pi}{\sqrt{3}}), -\mathbf{k}_1, \) and \( -\mathbf{k}_2 \). Condensation of \( \mathbf{e} \) particle can therefore lead to antiferromagnetic order. Two-spinon spectrum minima: \( \mathbf{Q}_1 = \mathbf{k}_2 - \mathbf{k}_1 = (\frac{2\pi}{3}, 0), \mathbf{Q}_2 = \mathbf{k}_1 - (-\mathbf{k}_1) = (\frac{\pi}{6}, \frac{\pi}{\sqrt{3}}), \mathbf{Q}_3 = \mathbf{k}_2 - (-\mathbf{k}_2) = (\frac{5\pi}{6}, \frac{\pi}{\sqrt{3}}), \mathbf{Q}_4 = \mathbf{k}_1 - \mathbf{k}_2 = (-\frac{\pi}{3}, 0), \mathbf{Q}_5 = -\mathbf{k}_1 - \mathbf{k}_2 = (-\frac{\pi}{3}, -\frac{\pi}{\sqrt{3}}), \) and \( \mathbf{Q}_6 = (-\mathbf{k}_2) - \mathbf{k}_2 = (\frac{\pi}{3}, -\frac{\pi}{\sqrt{3}}) \). These six vectors form another hexagon. The enlarged unit cell is \( 2\sqrt{3} \times 2\sqrt{3} \).

### b. Mean field theory of \( f \) particle

The PSG for the \( f \) particle is \( P^f = (0, 0, 1) \). The hopping term is equal for every bond. The pairing term follows the pattern shown in Fig. 7.

The mean field Ansatz is

\[
H_M = -\mu \sum_i f_i^\dagger f_i - i \sum_{\langle ij \rangle} (f_i^\dagger f_j + H.c.) - \sum_{\langle ij \rangle} (\Delta_{ij}^f f_i f_j + H.c.). \quad (C24)
\]

We need to fix the filling \( \langle f_i^\dagger f_i \rangle = \frac{1}{6} \). The pairing Ansatz is \( \Delta_{ij} = -\Delta_{ji} \) with \( |\Delta_{ij}| = \Delta \):

\[
H = \frac{1}{2} \sum_{k \in BZ} \langle f^\dagger(k), f(-k) \rangle H(k) \langle f(k), f^\dagger(-k) \rangle \quad (C25)
\]

with

\[
H(k) = \begin{pmatrix}
\xi(k) & \Delta(k)^* \\
\Delta(k) & -\xi(-k)
\end{pmatrix} \quad (C26)
\]

Let us define \( k_1 = k \cdot a_2 = k_x, k_2 = k \cdot a_2 = -\frac{1}{2}k_x + \frac{\sqrt{3}}{2}k_y \), and \( k_3 = k \cdot (a_1 + a_2) = \frac{1}{2}k_x + \frac{\sqrt{3}}{2}k_y \). We have

\[
\epsilon(k) = -2\epsilon_b (\cos k_1 + \cos k_2 + \cos k_3), \quad (C27)
\]

\[
\Delta(k) = 2|\Delta| (\sin k_1 + \sin k_2 - \sin k_3). \quad (C28)
\]

The dispersion is

\[
E(k) = \sqrt{[\epsilon(k) - \mu]^2 + 4\Delta^2 (\sin k_1 + \sin k_2 - \sin k_3)^2}. \quad (C29)
\]

Self-consistently we find \( \Delta = 3.7522J \) with mean field energy \( E_M = -0.02039 \times 42J, \mu = -7.095J \).
