Radiative Decay Modes of the $D^0$ Meson

CLEO Collaboration

(April 14, 2018)

Abstract

In this paper we describe a search for four radiative decay modes of the $D^0$ meson: $D^0 \rightarrow \phi \gamma$, $D^0 \rightarrow \omega \gamma$, $D^0 \rightarrow K^* \gamma$, and $D^0 \rightarrow \rho^0 \gamma$. We obtain 90% CL upper limits on the branching ratios of these modes of $1.9 \times 10^{-4}$, $2.4 \times 10^{-4}$, $7.6 \times 10^{-4}$ and $2.4 \times 10^{-4}$ respectively.

I. INTRODUCTION

Motivated by the successful CLEO II search for $b \to s\gamma$ decays [1], we have looked for analogous decays in the charm sector. In this paper we consider decays of the pseudo-scalar $D^0$ meson to final states consisting of a vector meson ($\phi, \omega, \bar{K}^* \text{or} \rho$) plus a photon.

Unlike $b \to s\gamma$ decays, the short-range amplitudes relevant to $c \to u\gamma$ are expected to be overwhelmed by much larger long-range electro-magnetic effects. The dominant diagrams describing these electro-magnetic amplitudes are shown in Figure 1. In each case, a pair of vector mesons is produced. Providing the quantum numbers are correct, one of these can couple to a photon. The phenomenology of such interactions, called “Vector Meson Dominance” (VMD), has been well studied [2]. Using VMD, one can make rough estimates of the expected rates for the modes studied in this paper. If the coupling of the photon to the transverse component of a $\rho^0$ results in a vector conversion with about 1% probability, we can use the Particle Data Group [3] value for the $D^0 \to \phi\rho$ branching ratio, $(2.6 \pm 0.8) \times 10^{-3}$, and expect that $\text{BR}(D^0 \to \phi\gamma)$ is about $2.6 \times 10^{-5} \cdot f_T$, where $f_T$ is the fraction of $\rho^0$s produced in the decay of the $D^0$ which are transversely polarized. Detailed calculations of the long-range, $W$-exchange and other contributing processes have been published by several groups [4–8]. The predictions range from $10^{-4}$ to $10^{-6}$ and are listed in Table I.

In the $b$ sector, observation of the decay $B \to K^{*+}\gamma$ at the measured rate provided compelling evidence for the existence of a “penguin” contribution to the $B$ mesons decay amplitude into this channel. The analogous short range penguin diagrams for the radiative decay of $D^0$ mesons are expected to contribute at the level of $\text{BR}(c \to u\gamma) = 10^{-11} - 10^{-8}$ [4,9], making them relatively unimportant.

The long range electro-magnetic contributions that are expected to dominate $D^0 \to V\gamma$ decay amplitudes also contribute in the $b$ sector. Their contribution to $B \to K^{*+}\gamma$, for example, may be as big as 20% [10]. It is hoped that a study of these effects in the charm sector can improve our understanding of their relevance to bottom decay.

The CLEO collaboration has recently published a complimentary analysis searching for flavor changing neutral currents in $D^0 \to Xl^+l^-$ decays [11].

II. DATASET AND EVENT SELECTION

The data used for the analysis described in this paper were acquired with the CLEO II detector [12] at the Cornell Electron Storage Ring (CESR), and represents a total integrated luminosity of 4.8fb$^{-1}$.

When searching for $D^0 \to V\gamma$ decays we apply several selection criteria on both the photon and vector meson candidates before attempting to reconstruct the $D^0$ [13]. We look for $\phi \to K^+K^-$ and require $1010 < M_{KK}(\text{MeV}/c^2) < 1030$. We also demand that the time of flight and specific ionization of both $\phi$ daughter tracks be consistent with Kaon hypotheses. We require $\omega$ candidates to decay into $\pi^+\pi^-\pi^0$ and have $763 < M_{3\pi}(\text{MeV}/c^2) < 801$. Both photons from the $\pi^0$ are required to be in the central region of the detector, $|\cos(\theta_{\gamma})| < 0.71$, and the $\gamma\gamma$ invariant mass must be consistent with a $\pi^0$ with $\chi^2 < 4.8$. To improve the measurement of the $\pi^0$ 4-vector, the photons are kinematically fit to the known $\pi^0$ mass.
We look for $\bar{K}^{*0} \rightarrow K^-\pi^+$ and require $842 < M_{K\pi} (\text{MeV}/c^2) < 942$. In this mode we also make a cut on the decay angle of the daughter particles in the $\bar{K}^*$ rest frame, requiring $|\cos(\theta_{\nu\gamma})| < 0.8$, since signal events should follow a $\sin^2(\theta_{\nu\gamma})$ distribution due to angular momentum conservation. Finally, we reconstruct $\rho$’s through the decay $\rho \rightarrow \pi^+\pi^-$ and require $620 < M_{\pi\pi} (\text{MeV}/c^2) < 920$.

In all cases we require that the “radiative” photon be in the central region of the calorimeter, have an energy greater than 830 MeV, and have a calorimeter shower isolated from charged tracks in the event. To avoid background from $\pi^0$ decays we veto photons that are part of a $\pi^0$ candidate with $\chi^2 < 15.3$.

In this analysis, all $D^0$ candidates are required to come from a $D^{*+} \rightarrow D^0\pi^+$ decay. The additional kinematic constraint provided by the $D^*$ is used to significantly reduce the otherwise large combinatoric background. We require the reconstructed mass difference between the $D^{*+}$ and the $D^0$, $\Delta M = M(D^{*+}) - M(D^0)$, to be between 144.3 MeV/$c^2$ and 146.5 MeV/$c^2$. To further reduce the background, we demand that $X_{D^*} > 0.625$, where $X_{D^*}$ is defined to be the momentum of the candidate $D^*$ divided by the maximum possible $D^*$ momentum.

The specific values of the cuts discussed above were chosen after a systematic study of $(\text{signal})^2/(\text{background})$ for each of the modes, using large samples of GEANT based Monte-Carlo data to model each specific signal as well as the background.

### III. BACKGROUNDS

To learn about possible sources of background for each of the four decay modes, a large sample of Monte-Carlo generated $e^+e^- \rightarrow q\bar{q}$ events was analyzed. The predominant background source found was real $D^{*+} \rightarrow D^0\pi^+$ decays where the $D^0$ decayed in channels involving $\pi^0$’s, which in turn decayed such that one of the photons had very little energy and went undetected. Since the $D^*$ decay in the above sequence is real, backgrounds of this kind will result in a false signal that peaks in the mass difference ($\Delta M$) distribution. Additional peaking in the $D^0$ mass spectrum will depend on kinematics.

This type of background is most severe for the $D^0 \rightarrow \bar{K}^*\gamma$ analysis because poorly reconstructed $D^0 \rightarrow K^-\pi^+\pi^0$ decays, where one of the $\pi^0$’s photons is missed, will peak in the $D^0$ signal region. Figure 2 shows the $D^0$ mass distribution for a set of $D^0 \rightarrow K^-\pi^+\pi^0$ events analyzed as $D^0 \rightarrow \bar{K}^*\gamma$.

In the case of $D^0 \rightarrow \rho\gamma$ the problem is less severe since there is no background decay mode which peaks in the signal region of our invariant mass distribution, although misreconstructed $D^0 \rightarrow K^-\pi^+\pi^0$ events cause the upward distortion of the $D^0$ invariant mass spectrum just below the expected $D^0$ mass. Figure 8 shows the distribution of these events when analyzed as $D^0 \rightarrow \rho\gamma$.

For the modes $D^0 \rightarrow \omega\gamma$ and $D^0 \rightarrow \phi\gamma$ there are no $D^0$ decay modes with large enough branching ratios to cause noticeable peaking in the reconstructed invariant mass distribution, hence we expect the background in the $D^0$ mass spectra of these to be smooth.
IV. SIGNAL YIELDS AND LIMITS

All yields were obtained by fitting the \( D^0 \) mass spectra. The signal in all cases was parameterized by a double bifurcated Gaussian whose mean and width were determined using Monte-Carlo. The background shape used depended on the mode. In the cases of \( D^0 \to \phi\gamma \) and \( D^0 \to \omega\gamma \) the background is expected to be smooth and likelihood fits were done using simple linear background. The data and fits for these modes are shown in Figures 4 and 5.

In the cases of \( D^0 \to \rho\gamma \) and \( D^0 \to \bar{K}^*\gamma \), we know the background shape is significantly modified by misreconstructed \( D^0 \to K^-\pi^+\pi^0 \) decays. Using Monte-Carlo, we determined the magnitude and shape of this contribution to the \( D^0 \) invariant mass spectrum, and in both cases included an additional component in our fits to compensate. The absolute normalization of this additional component was determined from a previous analysis of \( D^0 \to K^-\pi^+\pi^0 \) decays \[15\]. Figures 6 and 7(b) show the mass spectra and fits for these modes after subtracting the contribution from misreconstructed \( D^0 \to K^-\pi^+\pi^0 \).

The results are summarized in Table I. The efficiency for each mode was determined by analyzing samples of GEANT \[14\] based Monte-Carlo “signal” events, and is also presented in Table I. To obtain branching ratios from the efficiency corrected yields we performed a parallel analysis looking for \( D^{*-} \to D^0\pi^+, D^0 \to K^-\pi^+ \) decays. Our yield in this mode was 13,077 ± 124 events with an overall analysis efficiency of (16.9 ± 0.2) %, determined using Monte-Carlo. Using the PDG value of (3.86 ± 0.14) % for the \( D^0 \to K^-\pi^+ \) branching ratio we find the initial number of \( D^{*-} \to D^0\pi^+ \) decays in our data sample was \((2005 \pm 77) \times 10^3\).

V. SYSTEMATIC ERRORS

Several sources of possible systematic error were investigated, and the results are presented in Table I. With the exception of \( D^0 \to \omega\gamma \), the uncertainty in each case is dominated by uncertainties in fitting. To investigate this error we systematically changed either the combinatorial background shape, the normalization of the \( D^0 \to K^-\pi^+\pi^0 \) background component (in the \( \rho\gamma \) and \( \bar{K}^*\gamma \) cases only), the signal shape, and the number of bins used in the fits. Constant, linear and quadratic background functions were tried. Signal shapes were parameterized by Gaussian, Double Gaussian, bifurcated Gaussian and the double bifurcated Gaussian shapes. In each case we took the largest variation as our estimate of the systematic error.

As an additional check we excluded the signal region and fit only the background, using simple event counting in the signal region combined with Poisson statistics to obtain the upper limits. The result of this procedure for \( D^0 \to \bar{K}^*\gamma \), the mode having the otherwise biggest fitting uncertainties, is shown in Figure 8(a). In this case we fitted the \( D^0 \to \bar{K}^*\gamma \) data with a linear combinatorial component plus the absolutely normalized Monte-Carlo predicted \( D^0 \to K^-\pi^+\pi^0 \) background, excluding the region between 1.75 GeV/c^2 and 1.90 GeV/c^2 from the fit. We then count data and predicted background events in the same region to obtain a net yield of \(-33 \pm 24\). Using a conservative yield of 0 ± 24 events results in a 90% CL upper limit yield of 39 events, consistent with the original fitted result.
The vector meson mass cuts were studied by varying them to produce a 10\% change in efficiency and reanalyzing both data and Monte-Carlo with the new values to estimate the systematic error.

To estimate the errors associated with analysis requirements common to all of the studied modes (the $D^*-D$ mass difference and $D^*$ scaled momentum) while avoiding the problem of low statistics in the modes of interest, we used numbers obtained in a previous measurement of $D^0 \rightarrow K^-\pi^+\pi^0$.[15]

From a CLEO study of the decays $\eta \rightarrow \gamma\gamma$ and $\eta \rightarrow \pi^0\pi^0\pi^0$, we assign a 5.5\% systematic error for uncertainty in the overall $\pi^0$ finding efficiency and a 2.5\% uncertainty for each individual photon. The systematic error due to particle identification was estimated by removing that cut entirely and noting the change.

The systematic errors on the yield and the efficiency were treated separately when calculating the final upper limits. The efficiency and normalization errors were combined in quadrature and the efficiency was reduced by the resulting factor. The fitting systematic errors were used to increase the 90\% CL upper limit yields.

VI. CONCLUSION

Using data representing 4.8 fb$^{-1}$ of integrated luminosity acquired by the CLEO II detector at the Cornell Electron Storage Ring, we have conducted a search for radiative decay modes of the $D^0$ meson. The final results for the 90\% confidence level upper limit branching ratios for the modes studied are:

$$B(D^0 \rightarrow \phi\gamma) < 1.9 \times 10^{-4} \text{ @ 90\%CL}$$

$$B(D^0 \rightarrow \omega\gamma) < 2.4 \times 10^{-4} \text{ @ 90\%CL}$$

$$B(D^0 \rightarrow K^*\gamma) < 7.6 \times 10^{-4} \text{ @ 90\%CL}$$

$$B(D^0 \rightarrow \rho\gamma) < 2.4 \times 10^{-4} \text{ @ 90\%CL}$$

We note that all of these values are well above the theoretical expectations as shown in Table I. We hope that with more data from CESR, KEK and PEP-II B-factories it will be possible to provide improved measurements in the future.

We gratefully acknowledge the effort of the CESR staff in providing us with excellent luminosity and running conditions.
