ABSTRACT: In this paper we propose a method to gain access to the top-quark width which exploits off-shell regions in the process $e^+e^- \rightarrow W^+W^-b\bar{b}$. Working at next-to-leading order in QCD we show that carefully selected ratios of off-shell regions to on-shell regions in the reconstructed top and anti-top invariant mass spectra are, independently of the coupling $g_{t\bar{b}W}$, sensitive to the top-quark width. We explore this approach for different centre of mass energies and initial-state beam polarisations at $e^+e^-$ colliders and briefly comment on the applicability of this method for a measurement of the top-quark width at the LHC.

1 Introduction

The precise determination of top-quark properties is of high-priority at both hadron and lepton colliders, in particular due to the potential window to new physics offered by the top-quark sector. A future linear collider, such as the International Linear Collider, provides rich and exciting physics opportunities in the context of the Standard Model of particle physics (and beyond) and excellent prospects for accurately measuring many parameters relevant to the top sector. In this paper we propose a new method by which to bound the top-quark width, $\Gamma_t$, at centre of mass energies above threshold at a linear collider. The key idea is that in different regions of top-quark off-shellness, the cross section scales differently with respect to $\Gamma_t$ and this feature can be exploited to gain access to the width. For recent reviews of linear collider physics we refer to refs. and comprehensive reviews on top-quark physics at a linear collider can be found within refs.

It is well-known that, at a linear collider, the precise measurement of many top-quark properties, including that of a well-defined mass parameter, is optimally performed by studying the production of a top-quark pair near threshold, that is at a centre of mass
\( \sqrt{s} \sim 2m_t \sim 350 \text{ GeV} \) where the two top quarks are produced almost at rest and show strong binding effects. However, it is not the purpose of this paper to revisit this phase space region and we refer to refs. [6, 7] and the plethora of references therein for details and insights. A linear collider is likely to initially operate at a higher centre of mass energy \( \sqrt{s} \geq 500 \text{ GeV} \) [10], where top-quark pairs are produced in the continuum rather than at rest. There are a number of good reasons to start a linear collider run at a higher centre of mass energy including: making a measurement of the top-quark Yukawa coupling possible early on, recording of Higgsstrahlung and vector-boson fusion events and thus determining the couplings of the Higgs boson to heavy gauge bosons and, of course, better probing regions of phase space where new physics is more likely to appear. Further increasing the centre of mass energy of course enhances these prospects, for example, going from \( \sqrt{s} = 500 \text{ GeV} \) to \( \sqrt{s} = 600 \text{ GeV} \) increases the \( e^+e^- \rightarrow t\bar{t}H \) cross section by a factor of 4, which of course would be beneficial for the measurement of the top-quark Yukawa coupling. Therefore, despite the fact that a run at threshold will allow the extraction of theoretically more consistent and experimentally easier to measure top-quark properties, it is important to explore what possibilities for precise measurements of top-quark properties are offered by the continuum region.

Top-quark production in the continuum in \( e^+e^- \) collisions has and continues to be a subject of much theoretical attention. On-shell top-quark pair-production in the continuum is now known at next-to-next-to-leading order (NNLO) in QCD [11–21]. Relaxing the assumption of stable top quarks, top-pair production and decay in \( e^+e^- \) collisions has been studied in the narrow-width approximation in ref. [22]. The full process \( e^+e^- \rightarrow W^+W^-\bar{b}b \), in which intermediate top quarks can have arbitrary off-shellness was first computed at next-to-leading order (NLO) in ref. [23] and recently revisited in refs. [24, 25]. Leading order (LO) predictions for \( e^+e^- \rightarrow 6 \) fermions can be found in ref. [26]. A discussion of top-quark production with unstable top quarks in the continuum and in the regime of boosted tops, using a tower of effective field theories was provided in refs. [27, 28]. The latter compute the double-differential cross section with respect to the invariant masses of the two top quarks to next-to-leading-log, and show that in such a regime a well-defined mass parameter can, in principle, be determined with an accuracy of better than \( \mathcal{O}(\Lambda_{\text{QCD}}) \).

In this work we explore the idea of obtaining the top-quark width by exploiting the different resonance regions in the reconstructed top and anti-top invariant mass distributions that are present in the process \( e^+e^- \rightarrow W^+W^-\bar{b}b \). Top-pair and single top production co-exist in this full process and contributions to the different regions can be identified as double-resonant or single-resonant top-quark production, which intrinsically differ in their dependence on \( \Gamma_t \). For our investigation we simulate the fully-differential process using MadGraph5_aMC@NLO [29] at LO and NLO in QCD and emphasise that the full set of diagrams for \( e^+e^- \rightarrow W^+W^-\bar{b}b \) (i.e. those with two, one and no intermediate top-quark propagators) is included in the calculation. The method we present lies close in spirit with the method recently proposed to bound the Higgs-boson width [30–32].

Our paper is organized as follows: in the remainder of section 1, we motivate our approach by showing an analogy to the determination of the Higgs-boson width from off-shell regions and later transfer the idea to the case of the top-quark width, for which the current
theoretical and experimental knowledge is also briefly reviewed. In section 2 we discuss the process $e^+e^- \rightarrow W^+W^-b\bar{b}$ at NLO QCD, including our numerical setup and details on relevant distributions. We also provide a detailed examination of the reconstructed top-quark mass distribution, thus gaining insight into the structure of the different resonance regions of this process. In section 3 we show how the method for the Higgs boson is modified in the case of a pair of unstable top quarks. We apply this method to $e^+e^- \rightarrow W^+W^-b\bar{b}$ and illustrate how it enables one to gain access to the top-quark width. We additionally investigate the potential for enhanced sensitivities by exploiting polarised beams or higher centre of mass energies. Finally, we also discuss how our analysis may be improved in future studies and comment on the applicability of our method at the LHC. We end with our conclusions in section 4.

1.1 Off-shell regions and the Higgs-boson width

While the Higgs-boson width, $\Gamma_H$, is not the subject of this paper, we find it useful to briefly explain how measurements of off-shell regions can be used to place bounds on $\Gamma_H$, since it is the method applied in the case of the Higgs boson that motivated the study presented here. For a SM-like Higgs boson at 125 GeV, off-shell contributions to its decay into a pair of vector bosons ($V$) are sizeable [33–35] and measurements of this off-shell region offer the opportunity to indirectly constrain $\Gamma_H$ at the LHC. This can be achieved via the method proposed in refs. [30–32]. The key idea is that the ratio of off-shell to on-shell cross section measurements is sensitive to the total Higgs width. This can be inferred by examining how the cross sections in the different regions scale with the couplings involved in Higgs production and decay and how they scale with $\Gamma_H$. The on-shell cross section receives contributions from phase space where the invariant mass of the vector-boson pair is close to the Higgs-boson pole mass, $M(V,V) \sim m_H$, and scales as $\sigma_{VV}^{on} \sim g_{on}^2 \Gamma_H^{-1}$, where $g_{on}$ encodes all couplings involved in Higgs production and decay. In contrast, events with $M(V,V) \gg m_H$ contribute to the off-shell cross section, which scales as $\sigma_{VV}^{off} \sim g_{off}^2$, i.e. it is independent of the Higgs-boson width $\Gamma_H$.

Under the assumption that the couplings in the off-shell region $g_{off}$ can be related to those in the on-shell region $g_{on}$ an extraction of the width is possible simply by relating the on- and off-shell signal strength. For details in case of $e^+e^-$ collisions we refer to ref. [36], where off-shell effects in Higgs production at a linear collider were discussed. This method has been used at the LHC to achieve impressive bounds on $\Gamma_H$ after Run I, with CMS and ATLAS obtaining $\Gamma_H < 4.2\Gamma_H^{SM}$ and $\Gamma_H < (4.5–7.5)\Gamma_H^{SM}$ respectively [37, 38].

It must be emphasised that the extracted bound on the Higgs width ought to be taken with some care as it is based on an assumed relation between on- and off-shell couplings, namely that the on-shell and off-shell $\kappa$ factors are equal. The latter relation can be severely affected by Beyond-the-Standard Model (BSM) physics as discussed in refs. [41–44] for the LHC and in ref. [36] for a linear collider.

1.2 Off-shell regions and the top-quark width

In section 2 and section 3 we investigate whether a similar procedure of relating cross sections in different kinematic regimes can be applied to the case of top-quark production to

\footnote{For a definition of the $\kappa$-factors framework, we refer to refs. [39, 40].}
infer the total width of the top quark, \( \Gamma_t \). Since the different kinematic regions we wish to explore are actually regions of different on-/off-shellness of reconstructed top quarks, we have to consider the full process \( e^+e^- \rightarrow W^+W^-b\bar{b} \). This gives the relevant final state for the top-quark pair production process when the decay of the tops is included. The perturbative calculation we work with contains single-resonant and non-resonant contributions in addition to the usual double-resonant contributions and also includes full finite top-quark width effects. This means that in our calculation of this process, intermediate top quarks can in principle have arbitrary invariant mass.

As we will discuss in detail in the following sections, the key idea is that it is possible to gain access to the \( \Gamma_t \) by measuring the ratio of (suitably-defined) double-resonant and single-resonant regions in the double-differential cross section

\[
\frac{d^2\sigma^{e^+e^-\rightarrow W^+W^-b\bar{b}}}{dM(W^+,J_b)dM(W^-,J_{\bar{b}})}.
\]

\( M(W^+,J_b) \) and \( M(W^-,J_{\bar{b}}) \) are the top and anti-top masses reconstructed through the \( W \)-bosons and \( b/\bar{b} \)-flavoured jets, \( J_b/J_{\bar{b}} \), present in the final state. Crucially, the different resonance regions are influenced to varying degrees by all of the double-resonant (‘top-pair’), single-resonant (‘single top’) and non-resonant (‘no top’) sub-processes to \( e^+e^- \rightarrow W^+W^-b\bar{b} \).

Although the idea presented is similar to the method exploited to bound the Higgs width, there are a few differences which are important to point out:

1. In the top-quark case, we consider ratios of cross sections in single- and double-resonant regions which receive contributions from phase-space where one or two reconstructed top quarks are ‘nearly’ on-shell. However, in the Higgs-boson case, contributions from on-shell (resonant) Higgs-boson production are compared with far-off-shell Higgs-boson production.

2. In the case of the Higgs boson, in the on-shell region only one vector boson can be on its mass-shell and the off-shell region is rather large since both vector-bosons can go on-shell. In the case of top quark this enhancement of the ‘offshell’ region is not related to the on-shellness of both final-state \( W \)-bosons. Instead, the single-resonant region, though smaller than the double-resonant region, is still relatively large due to the (single) intermediate top quark being almost on-shell.

3. Unlike in the case of the Higgs boson, we work in a limited kinematic range rather close to the top-quark resonance peaks \( M(W^+,J_b) \), \( M(W^-,J_{\bar{b}}) \sim m_t \pm 50 \text{ GeV} \). In this range the influence of possible ‘high-mass’ BSM contributions is therefore limited and we can safely treat the involved couplings, most prominently the coupling of the top-quark to the \( W \) boson and the bottom quark, \( g_{b\bar{b}W} \), as constants.\(^2\)

\(^2\)Therefore, in contrast to the case of Higgs boson at the LHC, the assumed relation between on-shell and off-shell couplings is a much weaker one in the setup we consider here.
4. Whereas in the case of the Higgs boson the experimental sensitivity corresponds to a width which is multiple times the SM Higgs-boson width, here we only consider variations of the top-quark width up to $\pm 20\%$ of the SM value.

1.3 Status and prospects of top-quark width measurements

Before proceeding to a detailed description of our proposed method, we first comment on the theoretical knowledge of $t$ and its experimental measurement. At LO in the SM the top-quark width is dominated by the decay into the $W$ boson and a $b$ quark, which depends on the $g_{tbW}$-coupling as

$$
\Gamma(t \to Wb) = \left( \frac{g_{tbW}}{g} \right)^2 \frac{G_F m_t^3}{8\sqrt{2}\pi} \left( 1 - \frac{m_W^2}{m_t^2} \right)^2 \left( 1 + \frac{2m_W^2}{m_t^2} \right),
$$

where $g$ denotes the electroweak coupling of $SU(2)_L$, $G_F$ Fermi’s constant and $m_t$ and $m_W$ the top-quark mass and $W$ boson mass respectively (for simplicity we have set the bottom-quark mass to zero above). Apart from NLO QCD corrections [45–47] higher order QCD as well as electroweak corrections to $(t \to Wb)$ are known [48–53]. In the SM $g_{tbW}$ can be written as $gV_{tb}$ where $V_{tb}$ is the corresponding CKM matrix element. Since the branching fraction to a $W$ boson and a $b$ quark is almost 100%, the total top-quark width is almost linearly dependent on $g^2_{tbW}$.

Now we give a short summary of current measurements of $\Gamma_t$. Its value can be deduced from the measurement of the branching ratio $BR(t \to Wb)$ together with the partial decay width $\Gamma(t \to Wb)$. The former can be accessed through the ratio $R = BR(t \to Wb) / \sum_{q=d,s,b} BR(t \to Wq)$ measurable from top-pair production, which, being experimentally compatible with $R = 1$ [54], points towards $BR(t \to Wb) \sim 100\%$. This measurement also implies strong bounds on non-SM top-quark decays such as $t \to H^+ b$ [54]. The partial decay width can be indirectly determined through eq. (1.2) by a measurement of $g_{tbW}$, on which we subsequently focus. Whereas $g$ is known with great precision [54], the CKM matrix element can either be deduced from a global fit $V_{tb} = 0.99914 \pm 0.00005$ [54] assuming unitarity of the CKM matrix or from single top-quark production (whereas top-quark pair production is insensitive to $g_{tbW}$). The average of the single top-quark production cross section obtained by the Tevatron and the LHC experiments leads to $|V_{tb}| = 1.021 \pm 0.032$ [54], which can be used to indirectly extract the top-quark width to an accuracy of order 100 MeV. The coupling $g_{tbW}$ can be altered in models beyond the SM — we direct the interested reader to refs. [55, 56] for concrete examples in the context of a 2-Higgs-Doublet Model, the Minimal Supersymmetric Standard Model or top-color assisted Technicolor. Their effects are most dominant in the left-handed part of the coupling $g_{tbW}$ and are in the range of a few percent. We point out that though $g_{tbW}$ may differ from its SM value, this does not affect the validity of the assumption of equal on- and off-shell couplings discussed in section 1.2. For completeness we note that the best direct bound on $\Gamma_t$ is from CDF, which obtained $1.10 \text{ GeV} < \Gamma_t < 4.05 \text{ GeV}$ at 68% confidence level [57], from template fits of the reconstructed top masses in $t\bar{t}$ events.

At a linear collider $\Gamma_t$ can be directly deduced from top-quark pair production at threshold (see [6] and references therein). The dependence of the cross section on $\Gamma_t$ is
nicely illustrated in ref. [58]. Furthermore, the forward-backward asymmetry in $e^+e^- \rightarrow t\bar{t}$ near threshold shows a clear dependence on $\Gamma_t$ [8]. Refs. [59–61] report a projected accuracy of 20–30 MeV on $\Gamma_t$ from top-quark pair production measurements at threshold. In the continuum, due to the fine-resolution detectors and the cleaner environment at a linear collider, performing fits of the invariant-mass lineshape (reconstructed via the decay products of the top quark) provides a realistic method to precisely determine the top-quark width.\footnote{The dominant systematic experimental uncertainty for the direct extraction of $\Gamma_t$ at the Tevatron was the jet-energy resolution. At the LHC this will improve, however the clean environment at a Linear Collider will see this systematic error drop significantly. The large backgrounds at hadron colliders additionally complicate an extraction from fitting the lineshape.} We will comment on this extraction method in section 2.4, however we highlight that refs. [61, 62] estimate that, using reconstruction of the invariant mass at a linear collider, $\Gamma_t$ can be determined with a precision of 60–220 MeV for $\sqrt{s} = 500$ GeV and an integrated luminosity of 100 fb$^{-1}$.

As we will describe in the following sections, taking carefully chosen ratios of measurements of off-shell and on-shell regions (these will be quantified below) can also provide access to the top-quark width. The ratios are independent of explicit powers of the coupling $g_{tbW}$, in principle allowing one to disentangle the coupling $g_{tbW}$ and the width $\Gamma_t$.

2 $e^+e^- \rightarrow W^+W^-b\bar{b}$ at NLO in QCD

The process we consider here is

$$e^+e^- \rightarrow W^+W^- J_b J_{\bar{b}} + X.$$ (2.1)

Specifically, $J_b$ and $J_{\bar{b}}$ are bottom-flavoured jets containing at least a $b$ or a $\bar{b}$ parton respectively. The $W$-bosons in the final state are taken to be on-shell and stable (experimentally these can be reconstructed from their leptonic or hadronic decays).\footnote{The generation of the process at NLO, where the $W$-bosons are taken to be off-shell and decaying (for example $e^+e^- \rightarrow e^+\mu^-\nu_{\mu}\bar{\nu}_e J_b J_{\bar{b}} + X$) is exceptionally difficult to achieve, even with current state-of-the-art generators.} The process of eq. (2.1) makes it clear that we do not work in the approximation where top quarks are on-shell, but rather (much closer to reality) the presence of top quarks is inferred through a reconstruction of $b$-flavoured jets and $W$-bosons.

The process is generated at fixed-order (both LO and NLO-QCD) using the MADGRAPH5_aMC@NLO code [29] which uses MADLOOP [63] for the evaluation of the one-loop matrix element and MADFKS [64] (based on FKS subtraction [65]) to handle the singular regions of the real corrections. Additionally, the complex-mass scheme [66–68] is employed to consistently introduce the top-quark width. The bottom quark is considered to be stable and its mass is renormalized on-shell. We note that this process was first studied in ref. [23] and was briefly discussed in ref. [24]. Recently the authors of the WHIZARD EVENT GENERATOR [69, 70] have also investigated this process at NLO-QCD in ref. [25]. The Feynman diagrams contributing to this process include double-, single- and non-resonant diagrams and at the amplitude-squared level all of these interfere with each other. Tree-level examples of these are shown in figure 1.
Figure 1. Sample tree-level Feynman diagrams contributing to the full LO $e^+e^- \rightarrow W^+W^-b\bar{b}$ amplitude. These include (a) double-resonant, (b) & (c) single-resonant and (d) non-resonant diagrams.

The inclusive $W^+W^-b\bar{b}$ cross section is dominated by the double-resonant $t\bar{t}$ contributions, namely, contributions from diagrams such as diagram (a) in figure 1 which contains two resonant top-quark propagators. This is particularly the case near threshold. However, at centre of mass energies above threshold the relative contribution of single- and non-resonant terms (arising from diagrams such as (b) & (c) and (d) respectively of figure 1) increases [71]. Single and non-resonant contributions also become very relevant below threshold where the production of a resonant $t\bar{t}$ pair becomes kinematically suppressed, as discussed in ref. [55]. Therefore, both in the continuum as well as below threshold, having a faithful description of the full $W^+W^-b\bar{b}$ final state is of great importance.

As mentioned above, the complex-mass scheme is used to consistently introduce a complex mass at the Lagrangian level. This renormalization procedure replaces the bare top-quark mass, $m_{t,0}$ by a renormalized mass, $\mu_t$, and a counter-term, $\delta\mu_t$, both of which are complex,

$$m_{t,0} = \mu_t + \delta\mu_t,$$

where $\mu_t^2 = m_t^2 - im_t \Gamma_t$. In this scheme the value of the top-quark width is considered as an input and the counter-term is chosen such that $\mu_t^2$ corresponds to the pole of the renormalized top-quark propagator. Formally, this means that if one uses fixed-order predictions with the complex-mass scheme to extract the top-quark mass, then the mass parameter one is sensitive to is the pole mass, defined as $m_t^2 = \text{Re}[\mu_t^2]$. Accordingly, the employed
top-quark width is defined via $m_t \Gamma_t = -\text{Im}[\mu_t^2]$. The complex-mass scheme has already been used to compute NLO predictions for a number of processes involving unstable top quarks at hadron colliders [72–77].

### 2.1 Setup

We summarize the parameter and analysis setup used throughout this paper in this subsection. The results we present, with the exception of the discussion in section 3.4.2, are for a centre of mass energy of $\sqrt{s} = 500$ GeV. We begin our investigation for unpolarised initial-state electrons and positrons, but extend our analyses to polarised beams in section 3.4.1.

The numerical values of the relevant parameters used to produce our results are found in table 1. We use eq. (1.2), including bottom-quark mass effects, to obtain our numerical input value for the LO top-quark width and the result of ref. [46] to calculate the NLO top-quark width. In addition, we note that the assumption of a diagonal CKM matrix is made, namely we take $V_{tb} = 1$. The effect of a finite width of the $W$-boson is negligible for the observables we consider here, in particular since intermediate $W$-boson propagators are forced to be off-shell by kinematics. At NLO QCD the cross section develops a dependence on the renormalization scale $\mu_R$ (see section 2.2) and we employ a central scale choice of $\mu_R = m_t$ — a standard scale choice for the study of the $t\bar{t}$ process in $e^+e^-$ collisions. As we will see later, the inclusive cross section is very mildly dependent on this scale.

Partons in the final state are clustered into (a maximum of three) jets using the $k_t$-algorithm, as implemented in fastjet [78]. Tagging jets as $b$, $\bar{b}$ or light jets is done using the flavour information of partons in each jet that is available in our parton-level analysis. For most results we use a jet radius of $R_{\text{jet}} = 0.5$. However, since the different combinations through which gluon radiation can be clustered play an important role in the structure of the invariant-mass distributions (see below), the jet-radius parameter, $R_{\text{jet}}$, is varied (enlarged) in order to better understand the extent to which this affects $m_t$ or $\Gamma_t$ extractions. Minimal cuts of $p_T(J_b), p_T(J_{\bar{b}}) > 10$ GeV and $|\eta(J_b)|, |\eta(J_{\bar{b}})| < 4.5$ have been applied to the $b$-jets to define a typical fiducial region. This means that phase space points for which the $b$ and $\bar{b}$ partons are combined into the same jet are dropped in our analysis.

### 2.2 Inclusive and differential results

We first briefly discuss the dependence the cross sections have on the renormalization scale $\mu_R$. We note that at LO, since the amplitudes do not depend on $\alpha_s$ there is no dependence

| Parameter Setup |
|------------------|
| $m_t = 173.2$ GeV | $m_b = 4.75$ GeV | $m_W = 80.385$ GeV | $m_Z = 91.1886$ GeV |
| $m_H = 125$ GeV  | $\Gamma_Z = 2.505$ GeV | $\Gamma_H = 4.21$ MeV | $G_\mu = 1.1664 \times 10^{-5}$ GeV$^{-2}$ |

**Table 1.** Parameter choices.
on $\mu_R$. Of course, the NLO cross section picks up a dependence on $\mu_R$ and in order to study this dependence we use a fixed renormalization scale $\mu_R = \xi m_t$ and vary $\xi \in [0.1, 5]$. As illustrated in figure 2, both the fully-inclusive cross section as well as the fiducial cross section, defined according to the analysis cuts of section 2.1, only have a mild dependence on $\mu_R$. We note however that the NLO corrections themselves are important, enhancing the LO numbers by around 10 – 12%.

In figure 3 we show two example distributions, (a) the transverse momentum of the reconstructed top quark, $p_T(W^+, J_b)$ and (b) the transverse momentum of the $W^+W^-$ pair, $p_T(W^+, W^-)$. This is done to highlight that the code allows for the study of any infrared-safe differential observable that can be constructed using the full final state. While it is not the purpose of this paper to discuss the effects of NLO corrections to the $e^+e^- \rightarrow W^+W^-b\bar{b}$ process, we indicate in the lower panels of figure 3a and figure 3b that the NLO corrections do, for some observables, lead to non-constant differential $K$-factors. Off-shell and non-resonant effects will also play an important role in the tails of certain observables such as those in figure 3. However, to quantify the role of such effects would require (at least) a comparison with the process in the narrow-width approximation, $e^+e^- \rightarrow t\bar{t} \rightarrow W^+W^-b\bar{b}$, at NLO (including NLO corrections to both production at decay sub-processes), which is beyond the scope of this paper. Such comparisons at NLO for hadron-collider processes involving unstable top quarks can be found in refs. [73–75, 77, 79–81].

2.3 Structure of the invariant mass distributions of reconstructed top quarks

We now examine the distribution for $M(W^+, J_b)$, explaining the structure behind the shapes of the curves at LO and NLO. A better understanding of this distribution will be key to explaining the patterns in the results we present in section 2.4 and section 3.
we plot the invariant-mass distribution of the reconstructed top quark, $R_{\text{jet}} = 0.5$, $\Gamma_{\text{LO}} = 1.498 \, \text{GeV}$, $\Gamma_{\text{NLO}} = 1.369 \, \text{GeV}$, at $\sqrt{s} = 500 \, \text{GeV}$.

**Figure 3.** Distributions for the transverse momentum of (a) the reconstructed top quark, $p_T(W^+, J_b)$ and (b) the $W^+W^-$-pair, $p_T(W^+, W^-)$. Upper panels: the green curves indicate the LO distributions whilst the blue band shows the NLO result, where the band is obtained by varying the renormalisation scale in the range $\mu_R \in [m_t/2, 2m_t]$. Lower panels: the blue solid curves indicate the differential $K$-factor.

**Figure 4.** Distributions for the reconstructed top-quark mass, $M(W^+, J_b)$, in the range (a) $M(W^+, J_b) \in [120, 220] \, \text{GeV}$ and (b) $M(W^+, J_b) \in [162, 182] \, \text{GeV}$. Upper panels: the green curves indicate the LO distributions whilst the blue band shows the NLO result, where the band is obtained by varying the renormalisation scale in the range $\mu_R \in [m_t/2, 2m_t]$. The green and blue solid curves show the results for a jet radius of $R_{\text{jet}} = 0.5$ whilst the dashed gray curve shows the NLO distribution for $R_{\text{jet}} = 1.3$. Lower panels: the blue solid curves indicate the differential $K$-factor.

In figure 4 we plot the invariant-mass distribution of the reconstructed top quark, $M(W^+, J_b)$ at LO in green and at NLO in blue, for $R_{\text{jet}} = 0.5$ in the ranges (a) $[120, 220] \, \text{GeV}$ and (b) $[162, 182] \, \text{GeV}$. The shape of the LO curve around the peak, where the cross section is dominated by diagrams involving intermediate top quarks, is that of
tree-level/virtual production decay 
production emission decay emission

(a) (b) (c)

Figure 5. Schematic diagrams indicating structure of amplitudes in limit of on-shell top-quark production and decay.

a standard Breit-Wigner distribution. Moving out towards the tails of the distributions, non-resonant diagrams contribute to distort this shape. Going from LO to NLO one observes large differences between the two results, with the LO curve lying outside the NLO scale uncertainty band, particularly for the region $M(W^+, J_b) < m_t$.

To understand the reasons behind these large differences it is instructive to first consider the case of production and decay of a single on-shell top quark. In this case at LO it is always the case that the intermediate top-quark momentum is $p_t = p_W + p_b$, as illustrated in figure 5a, and all the cross section sits at $M(W^+, J_b) = m_t$. NLO virtual corrections to this process do not change the virtuality of the reconstructed invariant mass, namely for virtual contributions we still have $M(W^+, J_b) = m_t$. In contrast, NLO real corrections can change the virtuality of the reconstructed top. In the on-shell approximation for the real-emission contributions we can either have that the intermediate top momentum is equal to $p_t = p_W + p_b$, for the case of an emission from the production subprocess, or that the top momentum is equal to $p_t = p_W + p_b + p_g$, in the case of an emission from the top-decay subprocess. These two cases are illustrated schematically in figure 5b and figure 5c respectively.

When the momenta for the $b$ and $g$ momenta are fed to the jet algorithm the gluon momentum is either clustered together with or separately from the $b$-parton. In the case where there is an emission from the production subprocess, then either the gluon is clustered with the $b$-parton, thus increasing the reconstructed mass $M(W^+, J_b) > m_t$, or the gluon is not clustered with the $b$-parton, and the invariant mass remains at $M(W^+, J_b) = m_t$. In the case of a gluon emission from the decay subprocess, then either the gluon is clustered together with the $b$-parton meaning that the invariant mass remains at $M(W^+, J_b) = m_t$, or the gluon is clustered separately from the $b$-parton resulting in $M(W^+, J_b) < m_t$. Since the contributions that change the virtuality of the reconstructed top quark can only arise from real corrections at NLO (in the case of the narrow-width approximation that we consider here) they are positive contributions. In the case of on-shell top production and decay this leads to tails forming away from the peak at $M(W^+, J_b) = m_t$.

Having understood the structure in the case of on-shell top production, we move to the case of interest, namely off-shell top-pair production, or $W^+W^−b\bar{b}$ production. Since
intermediate top quarks are now generically off-shell and additionally non-resonant terms contribute, the distribution for the invariant mass receives contributions both above and below $M(W^+, J_b) = m_t$ starting at LO. The bulk of the cross section does still lie in or near the bin containing the point $M(W^+, J_b) = m_t$, indicating that the resonant contributions are dominant. For this reason, the one-loop virtual corrections also do not change the structure of the LO curve significantly, even though there are many contributing corrections in addition to the one-loop corrections to the production and decay subprocesses that we considered in our toy-setup.

On the other hand the real corrections, as in the on-shell case, can and do modify the LO shape of the reconstructed mass and the underlying reasons for this are precisely the same as those discussed in the case of an on-shell top quark. Firstly, a positive contribution is expected for $M(W^+, J_b) < m_t$, due to emissions from an off-shell resonant top, where $(p_W + p_b + p_g)^2 \sim m_t^2$, which are not captured in the $b$-jet. Secondly a similar positive contribution is expected in the region $M(W^+, J_b) > m_t$, due to emissions that do not change the virtuality of the intermediate resonant top, i.e. where $(p_W + p_b)^2 \sim m_t^2$, but which are however captured inside the $b$-jet.

From the above discussion it is clear that precisely how the distribution for $M(W^+, J_b)$ is affected by the NLO corrections is dependent on how real radiation is clustered into jets and in particular the radius of the jets. In figure 4 we also show the NLO distribution for $M(W^+, J_b)$ for $R_{jet} = 1.3$ (typically used in many linear collider top-quark analyses), where we see that the effect of increasing the jet radius moves the NLO curve down for $M(W^+, J_b) < m_t$ and up for $M(W^+, J_b) > m_t$. This is due to the fact that with a wider jet radius, on the one hand, one loses the gluon radiated from the top-decay subprocess outside the jet (leading to the lowering of the tail $M(W^+, J_b) < m_t$) less often, but on the other hand, more frequently captures radiation from the top-production subprocess or elsewhere into the $b$-jet (resulting in the increase of the tail $M(W^+, J_b) > m_t$).

Finally, we mention that given the impact of a single gluon emission on the shape of the distribution, it is evident that multiple gluon emissions during the parton-showering stage of a full event simulation will further affect the shape. In particular, parton-showering is expected to further broaden the lineshape of the reconstructed top quarks and is certainly an effect worth additional investigation (though lies beyond the scope of this work). We comment on this further in section 3.5.

2.4 Uncertainty on $m_t$ and $\Gamma_t$ extraction from kinematic reconstruction

In this subsection we briefly comment on a method commonly used to extract both the top-quark mass and width in the continuum. This consists of a simple fit of a Breit-Wigner (BW) function to the reconstructed mass peak $M(W^+, J_b)$ or $M(W^-, J_b)$ (see for example [61]). The method is usually applied to samples of simulated events where the underlying hard process is on-shell top-quark pair production $e^+e^- \rightarrow t\bar{t}$. These events are then supplemented with the corresponding LO decay of the top quarks by a parton shower and off-shellness is inserted through a BW-smearing of the virtuality of the intermediate top-quarks. Since the exact shapes for the reconstructed masses can be predicted at both LO and NLO, and these are not exact BW functions, it is of interest to investigate to what
extent fitting a BW function is a suitable method for extracting $m_t$ and $\Gamma_t$ or whether significant errors are introduced in doing so. Here we focus on the extraction of the top-quark mass and width using the full process $e^+e^- \rightarrow W^+W^-bb$ at NLO in QCD. Gluon emission at NLO in general broadens the peak, in particular at the invariant masses below the peak, and can thus potentially pull the extracted mass towards a smaller central value. As discussed earlier, the shape of the reconstructed mass shows a strong dependence on the jet radius used in the definition of $b$-jets.

We start with input values of $m_t = 173.2\, GeV$ and $\Gamma_t = 1.369\, GeV$ as input to MadGraph5\_aMC@NLO, using the latter to generate a distribution for $M(W^+, J_b)$ for $R_{\text{jet}} = \{0.5, 0.9, 1.3\}$. We then fit a BW function to these distributions extracting $m_t^{\text{meas}}$ and $\Gamma_t^{\text{meas}}$ as those parameters for which the BW function best models the distribution. This is done using a least-squares method and the goodness-of-fit is comparable (and very good) in all three cases. Specifically, the standard deviation for the extracted values of $m_t^{\text{meas}}$ and $\Gamma_t^{\text{meas}}$ is always below 60 MeV. We note that we have performed this simple exercise assuming perfect $b/b'$-jet tagging and reconstruction of $W^+$ and $W^-$. For $R_{\text{jet}} = 0.5$ we extract a mass and width of $m_t^{\text{meas}} = 173.00\, GeV$ and $\Gamma_t^{\text{meas}} = 1.92\, GeV$, for $R_{\text{jet}} = 0.9$ we find $m_t^{\text{meas}} = 173.14\, GeV$ and $\Gamma_t^{\text{meas}} = 1.55\, GeV$ and for $R_{\text{jet}} = 1.3$ we find $m_t^{\text{meas}} = 173.20\, GeV$ and $\Gamma_t^{\text{meas}} = 1.30\, GeV$. We see that with increasing $R_{\text{jet}}$ the extracted values for the mass and width approach the input values. This is due to the fact that with increasing $R_{\text{jet}}$, gluon radiation from intermediate top decays is more likely to be clustered in a way that least distorts the LO BW shape near the resonance peak, as discussed in section 2.3. In figure 6 we show the best-fit BW lineshapes as a function of the jet radius (in dashed blue, green and red) as well as the BW lineshape corresponding to the original input values used (in solid black).

To summarize, we would like to point out that a perturbative uncertainty of up to a few hundred MeV exists in the extraction of $\Gamma_t$ using a fit of a BW function (which essentially models the LO invariant mass) to an NLO $M(W^+, J_b)$ distribution. The size of this depends on the jet radius and should be taken into account when performing such extractions. The origin of the uncertainty appears to be predominantly due to gluon emissions distorting the LO lineshapes. This analysis is performed at fixed-order and despite the fact that parton showers capture some of the effects of hard radiation in the top-quark decay (and thus may decrease this uncertainty), we believe that the systematic error on extracting $\Gamma_t$ examined here will very likely remain until an extraction using the full NLO plus parton shower predictions of $e^+e^- \rightarrow W^+W^-bb$ (not presently available) is made. Until these new tools are utilised it should be kept in mind that template or BW-fitting extractions of the width based on simulations using LO top-quark decays (such as those performed for example in refs. [61, 62]) ought to include a potentially important systematic error due to these missing higher-order effects. We note that there is a corresponding, but smaller, uncertainty of about 200 MeV in the extraction of $m_t$.

We point out that it is known that the BW lineshape is additionally distorted by non-perturbative QCD effects. As explained in refs. [27, 28], these can shift the extracted top-quark mass and width to larger values; an effect that increases with the centre of mass energy. Control of such effects can be achieved through their encoding in universal soft functions.
3 Sensitivity of off-shell regions to the top-quark width

In this section we investigate the extent to which the idea of using the cross section in off-shell regions to probe or place bounds on the total width can be applied to top-pair production when measurements on the full final state of $W^+W^-b\bar{b}$ are made. This possibility, which does not depend on fitting a particular functional form to a lineshape, is interesting to explore as an alternative handle on $\Gamma_t$ in the continuum. Furthermore, the different choices one has in setting up this method in practice, could be simultaneously exploited to consistently extract a precise value for $\Gamma_t$.

Since there are two decaying top quarks, the method applied for the Higgs boson (discussed in section 1.1) has to be extended to consider the various resonance regions formed by both the top and anti-top invariant masses. Given top-quarks decay to $W$-bosons and $b$-quarks (measured as $b$-flavoured jets $J_b$ and $J_{\bar{b}}$ in experiments), the invariant masses one has to consider are those of reconstructed top quarks, namely $M(W^+, J_b)$ and $M(W^-, J_b)$. We first try to provide some insight into the structure of the $W^+W^-b\bar{b}$ cross section by considering different resonance regions of the reconstructed masses, $M(W^+, J_b)$ and $M(W^-, J_b)$. The cross section can be divided up into double, single- and non-resonant contributions, where these configurations can be quantified according to the value of the measured invariant masses as follows:

\begin{align}
\text{double resonant:} & \quad M(W^+, J_b) \sim m_t^2 \text{ and } M(W^-, J_b) \sim m_t^2 \\
\text{single resonant:} & \quad M(W^+, J_b) \sim m_t^2 \text{ and } \left\{ M(W^-, J_b) \ll m_t^2 \text{ or } M(W^-, J_b) \gg m_t^2 \right\} \\
\text{single resonant:} & \quad \left\{ M(W^+, J_b) \ll m_t^2 \text{ or } M(W^+, J_b) \gg m_t^2 \right\} \text{ and } M(W^-, J_b) \sim m_t^2 \\
\text{non resonant:} & \quad \left\{ M(W^+, J_b) \ll m_t^2 \text{ or } M(W^+, J_b) \gg m_t^2 \right\} \text{ and } \\
& \quad \left\{ M(W^-, J_b) \ll m_t^2 \text{ or } M(W^-, J_b) \gg m_t^2 \right\} .
\end{align}

We note that the way in which we have chosen to define the different resonance regions depends on being able to faithfully tag a $b$-jet and a $\bar{b}$-jet.\footnote{The precise way in which one divides up the phase space is of course arbitrary (see discussion later).} Although challenging, discriminating between bottom-quark and anti-quark jets does appear to be possible at a Linear Collider, see for example the discussion in ref. \cite{82} which proposes a novel quark-charge reconstruction algorithm to allow for such a selection. Since we consider the process with on-shell $W$-bosons, we have also made the assumption of perfectly reconstructed $W$-bosons. These are clearly theoretical idealisations, but they nevertheless allow us to explore effects and features that would be present in a setup that additionally includes detailed simulations of other experimental effects (combinatorics, detector effects, etc.).

3.1 Matrix-element structure in resonance regions

The full matrix element comprising of the complete set of diagrams has a non-trivial dependence on several couplings. However, the coupling structure of the amplitudes giving
the dominant contributions in the different resonant regions can be simplified. In the double-resonant region, as defined in eq. \((3.1)\), the leading contributions are given by the double-resonant diagrams, and in this region the matrix element squared can be written as

\[
|\mathcal{M}^{\text{DR}}|^2 = \sum_{V \in \{\gamma,Z\}} g_{ee}V g_{tt}V A_V^{\text{DR}} \left( \frac{g_{bW}^4}{m_t \Gamma_t} \right)^2 + \text{subleading terms},
\]

with \(A_V^{\text{DR}}\) denoting the amplitude for \(e^+e^- \to V \to W^+W^-b\bar{b}\) (see figure 1a).\(^7\) In the above equation we have factored out the dependence of the amplitudes on \(g_{bW}\) as well as the denominators of the top-quark propagators which lead to the explicit factors of \(\Gamma_t\).\(^8\)

In each of the single-resonant regions defined in eq. \((3.1)\), the leading contributions arise from a linear combination of double- and single-resonant amplitudes and the matrix element squared in these regions can be written schematically as

\[
|\mathcal{M}^{\text{SR}}|^2 = \sum_{V \in \{\gamma,Z\}} g_{ee}V g_{tt}V A_V^{\text{DR}} + \sum_{V \in \{\gamma,Z\}} \sum_{j \in \{b,W\}} g_{ee}V g_{jj}V A_V^{\text{SR}j} + g_{ee}W A_W^{\text{SR}} \left( \frac{g_{bW}^4}{m_t \Gamma_t} \right)^2 + \text{subleading terms}.
\]

\(A_V^{\text{SR}j}\) and \(A_W^{\text{SR}}\) are amplitudes arising from diagrams with a single-resonant top quark, such as those in figure 1b and figure 1c respectively. The structure above can be understood

\(^7\)The couplings \(g_{ijk}\) arise from the Feynman rules for the vertices involving the particles \(i, j\) and \(k\).

\(^8\)Note we have used the standard expansion

\[
\frac{1}{(p_X - m_X)^2 + m_X^2 p_X^2} \to \frac{1}{m_X^2} \delta(p_X^2 - m_X^2) + O\left(\frac{p_X^4}{m_X^6}\right)
\]

which holds in the limit \(p_X^2 \to m_X^2\) applied at the matrix element squared level.
as comprising of the single-resonant component of the double-resonant amplitudes (see figure 1a) and contributions from the single-resonant amplitudes themselves (see figure 1b and figure 1c). Given that only one reconstructed top is resonant, the matrix element scales as $\Gamma_t^{-1}$, however, interestingly, these contributions scale with the same power of $g_{tbW}$ as for the double-resonant case.

We now consider the ratio of the single-resonant and double-resonant region, which, following previous arguments is insensitive to explicit powers of the coupling $g_{tbW}$. However, this ratio is (up to subleading terms) linearly dependent on the width,

$$\frac{\sigma_{\text{single-resonant}}}{\sigma_{\text{double-resonant}}} \propto \Gamma_t. \quad (3.4)$$

This means that the ratio we consider above indeed is a probe of $\Gamma_t$ and is largely independent of variations in $g_{tbW}$. Of course, $\Gamma_t$ is itself sensitive to departures of $g_{tbW}$ from the SM value, but may also change without modifications to the $g_{tbW}$ coupling and the latter possibility is one we wish to allow for. The statement of eq. (3.4) holds at leading order and as we will see requires some refining when taking into account higher orders. It is also dependent on the assumption that all couplings involved in the process take their SM values. Should the couplings $g_{ttV}$ differ from their SM values, the ratio of single- and double-resonant contributions will in general be altered and the determination of the top-quark width becomes more involved. We note that subsequently when varying the top-quark width $\Gamma_t$ we hold the coupling $g_{tbW}$ fixed at its SM value. A priori, a common rescaling of $g_{tbW} \rightarrow \xi g_{tbW}$ and $\Gamma_t \rightarrow \xi^2 \Gamma_t$ leaves the double-resonant squared matrix element invariant, whereas the single-resonant region is rescaled. Therefore, eq. (3.4) provides the relevant counterpart ratio in the process $e^+e^- \rightarrow W^+W^-b\bar{b}$ that corresponds to the ratio taken in studies for the Higgs-boson width.

The sets of amplitudes we have isolated in eqs. (3.2) and (3.3) are not themselves gauge-invariant; gauge invariance is restored once all subleading terms are included, which of course is the case for the full amplitudes we actually work with. However, it is nevertheless true that the amplitudes written down in these equations give the leading contributions in the double- and single-resonant regions. We note that approaches such as the pole expansion [83, 84] or an effective theory expansion [81, 85, 86] provide gauge-invariant methods to compute cross sections to higher order in the different resonance regions without having to consider the full final-state amplitude. In such expansions the dominant terms in double- and single-resonant regions indeed receive their contributions from eqs. (3.2) and (3.3). This therefore argues strongly in favour of the scaling of the ratio in eq. (3.4) as well as for it being virtually independent of $g_{tbW}$.

3.2 Dividing up the cross section

In the previous subsection we argued that the ratio of single-resonant to double-resonant cross sections may provide a handle on the top-quark width. Here we set up a feasibility study of such a measurement, discussing in particular the care required in choosing the resonance regions.
According to the discussion above and in particular eq. (3.1) the cross section for $e^+e^- \rightarrow W^+W^-b\bar{b}$ can be divided up into double, single- and non-resonant regions in the double-differential distribution $d^2\sigma/dM(W^+,J_b)dM(W^-,J_b)$. We define reconstructed top and anti-top quarks to be resonant if $M(W^+,J_b) \in [M_{\text{min}},M_{\text{max}}]$ GeV and $M(W^-,J_b) \in [M_{\text{min}},M_{\text{max}}]$ GeV respectively. The cross section resonance regions can then be categorized as

- **double resonant (DR):** $M(W^+,J_b) \in [M_{\text{min}},M_{\text{max}}]$ and $M(W^-,J_b) \in [M_{\text{min}},M_{\text{max}}]
- **single resonant 1 (SR1):** $M(W^+,J_b) \in [M_{\text{min}},M_{\text{max}}]$ and $M(W^-,J_b) > M_{\text{max}}$
  or $M(W^+,J_b) > M_{\text{max}}$ and $M(W^-,J_b) \in [M_{\text{min}},M_{\text{max}}]$
- **single resonant 2 (SR2):** $M(W^+,J_b) \in [M_{\text{min}},M_{\text{max}}]$ and $M(W^-,J_b) < M_{\text{min}}$
  or $M(W^+,J_b) < M_{\text{min}}$ and $M(W^-,J_b) \in [M_{\text{min}},M_{\text{max}}]$. (3.5)

We use the notation $\sigma^{\text{DR}}$, $\sigma^{\text{SR1}}$, $\sigma^{\text{SR2}}$ to denote the cross section of the $W^+W^-b\bar{b}$ process in these phase space regions. We have chosen not to list the non-resonant regions above. This is because for the setup we study, the cross sections for these are negligible compared to those in the DR, SR1 and SR2 regions and therefore we do not consider them useful in this context. The boundaries $(M_{\text{min}},M_{\text{max}})$ determine the size of the resonant region for each reconstructed top quark. The exact values are of course arbitrary and we vary them in three sets $(M_{\text{min}},M_{\text{max}}) \in \{(165,180),(160,185),(155,190)\}$ GeV.\(^9\)

The reason for having two separate single-resonant (SR1 and SR2) regions has to do with higher-order corrections to the cross section. As was carefully explained in section 2.3 and is clearly visible in figure 4, in the region of $M(W^+,J_b), M(W^-,J_b) < M_{\text{min}}$ the cross section is highly sensitive to additional gluon radiation from the decay products of a resonant intermediate top quark. This means that the SR2 region will tend to receive very large NLO corrections from double-resonant real contributions in which gluon emissions are not captured in the appropriate $b$ or $\bar{b}$ jet. As such the SR2 region is likely to suffer from a significantly larger renormalization scale dependence than the SR1 region. It is therefore, in practice, much less sensitive to variations in the top-quark width than a LO analysis may naively find. Since the size of this effect is dependent on the choice made for $R_{\text{jet}}$ we investigate the impact of varying the jet radius has on the final results.

We study the impact on the structure of the cross section when varying the SM top-quark width by $\pm 20\%$ and fixing the coupling $g_{bW}$. The LO cross section is independent of $\mu_{\text{R}}$ since the tree-level diagrams do not depend on $\alpha_s$. The NLO cross section does however depend on the renormalization scales and this dependence must be quantified if a reliable estimate of the sensitivity to $\Gamma_t$ is to be made.

In figure 7a we plot the dependence on $\mu_{\text{R}}$ of the fiducial cross section (thick solid blue), as well as the $\mu_{\text{R}}$-dependence of its double- and resonant sub-regions: DR (thin

\(^9\)We note that $(M_{\text{min}},M_{\text{max}}) = (165,180)$ GeV (roughly) represent the boundaries outside which the effects of $\Gamma_t$ in the Breit-Wigner propagator are smaller than 1%, i.e. for $M > 160$ GeV or $M > 185$ GeV, we have that $(m_t^2 - m_{\text{min}}^2)^2 + m_t^2\Gamma_t^2)/(m_t^2 - m_{\text{max}}^2)^2 < 1.01$.\)
solid blue), SR1 (long dashed blue) and SR2 (dotted blue). As also seen in figure 2, the total fiducial cross section is only very mildly dependent on $\mu_R$. However, figure 7a reveals that both DR and SR2 cross sections carry a dependence on $\mu_R$ and, moreover, that their dependence goes in opposite directions. This crucially means that the ratio SR2/DR has a large dependence on $\mu_R$, thus making it essentially insensitive within uncertainties to the relatively small variations in $\Gamma_t$ we consider. On the other hand, the SR1 region is largely independent on $\mu_R$, making the ratio SR1/DR a potentially good one for probing $\Gamma_t$. These patterns will be confirmed in the figures that follow. We note that similar conclusions as for the SR2 region hold for the total single-resonant region SR1+SR2 since the latter is dominated in size and in scale-dependence by the SR2 region (see the short dashed gray curve in figure 7a). For this reason we do not consider the full single-resonant region any further.

Figure 7b shows the $\Gamma_t$-dependence of the DR, SR1 and SR2 regions at LO (green) and NLO (blue). The clear $1/T^2$ behaviour of the double-resonant region both at LO and NLO illustrates that while varying the top-quark width we hold $g_{tW}$ fixed. This also illustrates our earlier arguments that the NLO corrections to the SR2-region cross section are indeed very large, whilst the corrections to SR1 show a better behaviour. Whilst the actual size of NLO corrections in each region is dependent on $R_{\text{jet}}$, these observations are generically true over all values of $R_{\text{jet}}$ that we have considered (i.e. $R_{\text{jet}} \in [0.5, 1.3]$). As also anticipated the $\sigma_{\text{SR2}}$ contribution shows a sizeable dependence on $\mu_R$, whilst $\sigma_{\text{SR1}}$ appears relatively unaffected by the variation.

### 3.3 Bounding the top-quark width

With the understanding of the structure of NLO corrections gained in section 2.3 as well as the patterns of the scale dependence of the various resonance regions explored in the
previous subsection, we can now move to studying the ratios of interest. Specifically we examine the cross section ratios:

\[
\frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \quad \text{and} \quad \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}}.
\]  

(3.6)

In order to verify the independence of our ratios on the coupling \( g_{tbW} \), we have checked numerically that varying \( g_{tbW} \) by \( \pm 10\% \) while keeping \( \Gamma_t \) fixed, indeed leaves the ratios unchanged.

In each of the plots in figure 8 the ratios \( \frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \) (long dashes) and \( \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}} \) (short dashes) are shown. LO and NLO results are in green and blue respectively and the bands around the NLO results indicate the uncertainty due to \( \mu_R \)-variation. From left-to-right in figure 8 the jet radius parameter is varied, \( R_{\text{jet}} \in \{0.5, 1.3\} \), i.e. going left-to-right illustrates the effect of increasing the size of the jet-radius. From top-to-bottom in figure 8 we have varied the definition of the resonance region — specifically a reconstructed top is defined to be resonant if \( M(W^+, J_b) \in \{165, 180\}, \{160, 185\}, \{155, 190\} \) GeV, i.e. going top-to-bottom the resonance region is widened.

In general, it is observed that at LO and NLO both ratios \( \frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \) and \( \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}} \) display a roughly linear dependence on \( \Gamma_t \), as might be expected from the naive counting arguments given in the discussion preceding eq. (3.4). For the latter ratio however the dependence is actually much flatter, whereas the former ratio importantly shows a stronger dependence on the top-quark width (i.e. the gradient is steeper).

For \( R_{\text{jet}} = 0.5 \) at NLO, see plots (a), (c) and (e) of figure 8, the ratio \( \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}} \) suffers from a large \( \mu_R \)-variation uncertainty (of real emission origin as discussed previously). In contrast and as expected, \( \frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \) only has a small corresponding uncertainty for \( R_{\text{jet}} = 0.5 \). Widening the jet radius leads to the scale uncertainty increasing for \( \frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \) and decreasing for \( \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}} \). For the results with \( R_{\text{jet}} = 1.3 \) displayed in plots (b), (d) and (f) of figure 8, we see that the uncertainty bands of the two ratios have roughly the same thickness. As explained in section 2.3, the reason for this is that a larger jet radius means that less radiation is leaked out of the \( b \)-jet for emissions from the top decay whilst unfortunately allows more radiation into the \( b \)-jet when emissions come from elsewhere in the \( W^+W^- \) process. These two effects combine to increase the size of NLO corrections and scale dependence of \( M(W^+, J_b) < m_t \) and have the opposite effect for \( M(W^+, J_b) > m_t \), as we also saw in figure 4. The same reason lies behind the observed pattern that with increasing jet radius the ratios \( \frac{\sigma^{\text{SR1}}}{\sigma^{\text{DR}}} \) and \( \frac{\sigma^{\text{SR2}}}{\sigma^{\text{DR}}} \) are enhanced and diminished respectively. By minimising the amount of radiation not originating from resonant decaying tops ending up in the \( b \)-jets (i.e. identifying resonance regions in a way that is less sensitive to higher-order corrections), it is highly plausible that the use of modern jet-substructure techniques may help to control the behaviour of the SR1 region for increasing \( R_{\text{jet}} \). It is foreseen that this would improve the method presented in this paper.

As stressed above, precisely where one chooses to split the cross section into its various resonance regions is a little arbitrary and variations of this choice should be studied. In figure 8 going from top-to-bottom the ratios of cross sections decrease in size, however the pattern for the ratios of cross sections remains the same. This is due to the fact that by
\[ R = 0.3 \]

of the ratios of the single-resonant cross sections, SR1 (long dashed curves) and SR2 (short dashed curves) to the double-resonant, DR, cross section, see eq. (3.5) for definitions. Ratios of LO and NLO cross sections are shown in green and blue respectively and bands are obtained via variation of \( \mu_R \). The left-hand plots (a, c, e) show the results for \( R_{\text{jet}} = 0.5 \) whilst the right-hand plots (b, d, f) illustrate the results for \( R_{\text{jet}} = 1.3 \). The left-hand plots (a, c, e) show the results for \( \sqrt{s} = 500 \text{ GeV} \), \( (M_{\text{min}}, M_{\text{max}}) = (165, 180) \text{ GeV} \) and \( (M_{\text{min}}, M_{\text{max}}) = (155, 190) \text{ GeV} \), respectively. All results are for \( \sqrt{s} = 500 \text{ GeV} \).

\[ \text{Figure 8. widening the definition of the resonances one naturally reduces the single-resonant regions while at the same time increasing the double-resonant one. The patterns remain the same because we have chosen to widen the resonance window in a symmetric manner. Of course, one is free to pick different (e.g. asymmetric) resonance regions, however the patterns and results we present here are unlikely to change dramatically.

Table 2. Sensitivities on the top-quark width for different setups of the centre-of-mass energy $\sqrt{s}$, the polarisation, given as $(P_+, P_-)$, the jet radius $R_{\text{jet}}$ and the interval $(M_{\text{min}}, M_{\text{max}})$. See the text at the end of section 3.3 for further details.

Overall the ratio $\sigma^{SR1}/\sigma^{DR}$ exploiting the region $M(W^+, J_b) > m_t$ appears as the more useful of the two to probe $\Gamma_t$. The large scale dependence together with the flatness of the ratio $\sigma^{SR2}/\sigma^{DR}$ make this ratio rather unsuitable for a width-extraction.\footnote{Exactly the same conclusions hold for a ratio involving the total single-resonant region, namely $(\sigma^{SR1} + \sigma^{SR2})/\sigma^{DR}$.} To quantify the potential sensitivity this approach may achieve and to compare the different setups, we provide possible accuracies on $\Gamma_t$ in two scenarios. Firstly, we assume a measurement of the ratio of $\sigma^{SR1}/\sigma^{DR}$ with infinite experimental precision, which due to the scale uncertainty translates into an uncertainty $\Delta \Gamma_1^{\text{scale}}$. Secondly, we assume a fixed experimental error on the ratio $\sigma^{SR1}/\sigma^{DR}$ of $\pm 0.005$, which corresponds to an accuracy of 5–10% on the measurement of the ratio. This enlarges the uncertainty of $\Delta \Gamma_1^{\text{scale}}$ to $\Delta \Gamma_1$ as shown in table 2. The table also contains the results for these two scenarios for the collider setups discussed in section 3.4. From the information in table 2 we conclude that, in case of an unpolarised initial state and $\sqrt{s} = 500$ GeV, better sensitivities are obtained for a small jet radius $R_{\text{jet}}$. We also observe that while increasing the interval $(M_{\text{min}}, M_{\text{max}})$ generally improves the sensitivity $\Delta \Gamma_1^{\text{scale}}$, the actual number of events is diminished in the single-resonant region leading to a smaller value for the ratio $\sigma^{SR1}/\sigma^{DR}$. As expected, when assuming an absolute error on the measurement of the ratio, this smaller value results in larger uncertainties $\Delta \Gamma_1$.

We have checked that for $\sqrt{s} = 500$ GeV and an integrated luminosity of 500 fb$^{-1}$ several thousands of events can be recorded, even in the single-resonant region SR1. The difficulties of the method are thus not in collecting enough statistics, but in a proper
reconstruction of the invariant mass. We also emphasise here that varying the scale provides a handle for estimating the residual perturbative uncertainty due to missing higher-order effects. In order to check that this has not been underestimated in the variation of our fixed-scale choice, we also performed the same analysis using a dynamical scale choice for $\mu_R$, namely choosing it as the average of the transverse masses of the final state particles on an event-by-event basis. We find that the results with this functionally different scale choice are covered by the uncertainty bands presented in figure 8 and in table 2. However, the dependence on $\mu_R$ is not the only source of uncertainty present (other sources may include uncertainties in parton-showering and hadronization, mis-tagging $b$-jets, etc.) and the full error band may indeed be larger. We discuss this in greater detail in section 3.5.

3.4 Improved width extractions

There are a number of ways to exploit possible linear collider setups to improve the sensitivity of the method explored in the previous section on the top-quark width. The two ways we consider here are using polarised beams and increasing the centre of mass energy, both of which tend to enhance the proportion of single-resonant to double-resonant contributions to the $W^+W^-b\bar{b}$ cross section.

3.4.1 Exploiting polarised beams

So far, our discussion has been based on simulations where the helicities of the incoming electron and positron were averaged over. However, a powerful feature of a linear collider is the fact that the initial state electron and positron beams can be polarised. Given the electroweak nature of the primary interactions of the processes under consideration, the inclusive cross section $\sigma$ can be decomposed according to [87]

$$\sigma = \frac{1}{4} (1 - P_{e^+}) (1 + P_{e^-}) \sigma_{-1+1} + \frac{1}{4} (1 + P_{e^+}) (1 - P_{e^-}) \sigma_{+1-1}, \quad (3.7)$$

where $P_{e^+}$ and $P_{e^-}$ denote the relative polarisation of the positron and electron beam respectively. $\sigma_{xy}$ encodes the cross section obtained with fixed helicities $x$ for the positron $e^+$ and $y$ for the electron $e^-$. Whereas the double-resonant diagrams contribute to both parts $\sigma_{-1+1}$ and $\sigma_{+1-1}$ several single-resonant and non-resonant diagrams only contribute to the combination $\sigma_{+1-1}$. Therefore, the single-resonant contributions can be enhanced by choosing the $(P_{e^+}, P_{e^-}) = (+1, -1)$ combination. We note that eq. (3.7) is also valid at the level of differential cross sections, i.e. we can replace all occurrences of the inclusive cross section $\sigma$ with e.g. $d\sigma/dM(W^+, J_b)$ at LO and NLO in QCD. We obtained polarised initial states in MADGRAPH5_AMC@NLO by adapting the model files such as to select only left- or right-handed couplings appropriately. We have validated our results at LO through a comparison to results with explicit polarisations (available in the LO version of the MADGRAPH5_AMC@NLO code) and at NLO by ensuring that we could reproduce the unpolarised cross section using eq. (3.7).

In figure 9a we show the differential cross section as a function of $M(W^+, J_b)$ for the unpolarised initial state as discussed beforehand, but also for two common polarisa-
We find these to be significantly improved compared to the unpolarised case. We note that the results for $R_{\text{jet}} = 0.5$ (not shown) are similar.

Taking all of this into account, it is evident that the sensitivity to the top-quark width can thus be significantly increased by the combination $(P_{e^+}, P_{e^-}) = (-1, +1)$. For this particular case we show the corresponding sensitivity in figure 10 obtained for a jet radius of $R_{\text{jet}} = 0.5$. Compared to the unpolarised case (figure 8a) we see that not only is the ratio $\sigma^{\text{SR1}}/\sigma^{\text{DR}}$ increased in size, but also its gradient is visibly enhanced (by about 23% for the setup considered). We perform the exercise of extracting $\Gamma_t$ in the two scenarios described at the end of section 3.3 and indicate the corresponding accuracies in table 2. We find these to be significantly improved compared to the unpolarised case.

### 3.4.2 Exploiting a higher centre of mass energy

As mentioned in the introduction, increasing the centre of mass energy beyond $\sqrt{s} = 500\text{ GeV}$ is well-motivated, since this, for example, provides better access to the top-quark

---

11The chosen polarisation degrees are those foreseen for the current baseline design, however, higher polarisation degrees for both beams could be achieved at a later stage.
Yukawa coupling [7]. Hence, in this subsection we present the sensitivity on the top-quark width for $\sqrt{s} = 600$ GeV. Once again we study the ratios of eq. (3.6), showing these in figure 10b, and again using $R_{\text{jet}} = 0.5$. We again find that not only is the relevant ratio $\sigma_{\text{SR1}}/\sigma_{\text{DR}}$ increased in size, but additionally the sensitivity on the top-quark width is enhanced, with the gradient of the slope increased by about 38% in the setup considered. Even though the scale uncertainty increases in size (thus increasing $\Delta \Gamma^\text{scale}$), the accuracy on $\Gamma_t$ when an experimental error is included, $\Delta \Gamma_t$, is still slightly improved compared to the case of $\sqrt{s} = 500$ GeV due to the enhancement of the gradient. The relevant numbers on the sensitivity can be found in table 2.

3.5 Opportunities and limitations of the method

We have shown that the ratio $\sigma_{\text{SR1}}/\sigma_{\text{DR}}$ is a promising observable for extracting the top-quark width, independently from $g_{bW}$, in a generic analysis of the $W^+W^-b\bar{b}$ process at a linear collider. An extraction of $\Gamma_t$ for different choices of the resonance windows used (eq. (3.5)) not only provides an in-built consistency check on the method and measurements, but also (through the combination of these extractions) may allow for the shrinking of uncertainties in $\Gamma_t$. Furthermore, we emphasise that providing a method complementary to a lineshape fit, that additionally allows for deviations of $\Gamma_t$ independently of variations in $g_{bW}$, is of significant value. An interesting avenue to explore would also be to assume a fixed value for $\Gamma_t$ and investigate the extent to which our method can disentangle the $g_{ttV}$ couplings from $g_{bW}$ (top-pair production is sensitive to the product $g_{ttV}g_{bW}^2$).

The uncertainty in the extraction of $\Gamma_t$ using our method has been estimated by variation of the renormalization scale, $\mu_R$; a dependence which enters at NLO. In our fixed-order
simulations, this is the only handle available to estimate the perturbative uncertainty in the predictions and we have made sure to include this in our analysis. There are of course additional sources of uncertainty which can be quantified when a simulation that includes parton-showering and hadronization effects is performed. While a detailed study of these is beyond the scope of this work, we discuss such sources of uncertainty below, arguing that they should not significantly affect the underlying perturbative structures we have exploited in our method, hence not diminishing its usefulness.

It is now important to point out that for the investigation we have presented in this work some assumptions have been made. Firstly, we have assumed a perfect $b$ and $\bar{b}$ jet-tagging as well as a perfect reconstruction of $W$-bosons. A more sophisticated analysis could include errors due to mistagging etc. Such uncertainties are unlikely to affect the theory results strongly and can rather be included as an experimental error. An additional assumption we have made is that the couplings appearing in the amplitudes for $e^+e^- \rightarrow W^+W^-b\bar{b}$ all take their (fixed) SM values. Clearly if couplings such as $g_{\mu Z}$ were to differ from their SM value, then the ratios predicted would also change, thus skewing the extracted width. This potential problem can be overcome by using as inputs to our method, values for the couplings as constrained in other collider processes.

The simulation underlying this work is a parton-level simulation, namely one that does not include the effects of parton-showering and hadronization. These two steps beyond a fixed-order simulation are known to alter some distribution shapes significantly. While it is therefore important to extend our results to include these effects, and thus any potential shape distortions to invariant mass distributions we expect that, after parton-showering and hadronization, the changes to the resonance regions that arise from variations in $\Gamma_t$ will be very similar to those observed in our fixed-order analysis, and therefore that the ratios will remain a very good probe of $\Gamma_t$. Moreover, jet-substructure techniques could be employed to understand and control radiation in an event such that the split into the resonance regions and the structure of the cross section within these is not altered significantly from the fixed-order analysis we have discussed. Therefore, we fully expect that our conclusions and the usefulness of the method to be largely unaltered.

We end this section with a few comments regarding the applicability of this method for $\Gamma_t$-extraction at the LHC from the $pp \rightarrow W^+W^-b\bar{b}$ process. This process has received significant attention recently and NLO QCD corrections to the full process are known \cite{72, 74, 76, 77}. While certainly a possibility worth exploring (one which is however beyond the scope of this work) the proton-proton initiated process intrinsically contains some difficulties. Following the same arguments presented in section 3.1, the ratio of the leading parts of the squared matrix element in the single- and double-resonant regions will in principle also be sensitive to $\Gamma_t$. However, given that at LO the squared matrix element is proportional to $\alpha_s^2$ and that the predicted cross section additionally carries a dependence on a factorization scale, $\mu_F$, the uncertainty due to the variation of these scales is significantly

\footnote{This can be done within the framework of \textsc{MadGraph5}_\textsc{aMC@NLO} as well as that of the \textsc{WHIZARD Event Generator}, though the consistent matching to parton shower of the $W^+W^-b\bar{b}$ process is not totally straightforward and requires care due to the presence of intermediate coloured resonances (see the discussions in refs. \cite{88, 89}).}
larger than that observed in this study (see discussions in the references cited above), in particular for exclusive observables. Though the ratio \( \sigma_{SR1}/\sigma_{DR} \) may indeed be quite sensitive to \( \Gamma_t \), we feel it is very likely that the uncertainty on the ratio would make an extraction prohibitive in practice (much like we have demonstrated for the ratio \( \sigma_{SR2}/\sigma_{DR} \)), even using the state-of-the-art NLO computations. It is of course possible, that with some modifications or in combination with additional measurements, such ratios would also be useful in a hadron-collider environment.

4 Conclusions

We have performed a detailed study of the \( e^+e^- \to W^+W^-b\bar{b} \) process at NLO in QCD using \textsc{MadGraph5}_{\text{aMC@NLO}} to simulate the fixed-order results. In particular we have examined the structure of reconstructed top-quark masses which has allowed for a detailed understanding of the double-, single- and non-resonant contributions of the total cross section. We have used this to show that the ratio of single-resonant to double-resonant cross section contributions is sensitive to the top-quark width whilst simultaneously being independent of the \( g_{tbW} \) coupling. The central results of this article are the in-depth investigation of this ratio. We have shown in a typical linear collider analysis, that with a careful definition or choice of the single-resonant region of the cross section, that such a ratio is, also in practice, sensitive to the value of \( \Gamma_t \), and can be exploited to extract the width at an \( e^+e^- \) collider. We have explored the effects that variations in both the jet radius as well as in the resonance window (in which reconstructed top quarks are defined to be resonant) have on the ratios. Additionally, we showed that using polarised beams or higher centre of mass energies leads to an enhanced sensitivity to \( \Gamma_t \). In a study of the expected errors in the extraction of \( \Gamma_t \) using this method, we find that attainable accuracies of \(< 200\) MeV are possible with unpolarised beams at \( \sqrt{s} = 500\) GeV. We note that these are comparable to the accuracies quoted in the literature obtained from invariant-mass lineshape fitting, and that they can be significantly improved by exploiting polarised initial states.

Our study of the \( e^+e^- \to W^+W^-b\bar{b} \) process here has been restricted to fixed-order. The next step in extending this investigation is to include effects due to parton-showering and hadronization, which we look forward to investigating in future work.
