Anyons represent a third fundamental class of particles with fractional exchange statistics that interpolates, to some degree, between those of bosons and fermions having symmetric or antisymmetric wave functions under exchange [1, 2]. By contrast, the exchange of two anyons creates a phase factor $e^{i\theta}$ in the many-body wave function, where the statistical parameter $\theta$ can be of any value in the interval $(0, \pi)$. In the beginning anyons were thought to be relevant solely for two-dimensional systems. Describing the fractional quantum Hall effect experiments in particular, the quasiparticles could be viewed as anyons with $\theta$ fixed by the filling factor $\nu$ [3, 4]. With Haldane's generalized Pauli principle and definition of fractional statistics, however, the concept of anyons becomes important in arbitrary dimensions [5].

In one dimension, the physics of anyons might be studied successfully with ultra-cold atoms in optical lattices [6]. For example, one-dimensional (1D) anyon statistics can be implemented by bosons with occupation-dependent hopping amplitudes generated by assisted Raman tunneling [7]. An alternative route to create 1D anyons in an optical lattice exploits lattice-shaking-assisted tunneling against potential offsets generated by a combination of a static potential tilt and strong on-site interactions [9]. Thereby, advantageously, no additional lasers are required, except for those employed on creating optical lattices. However, in spite of the huge experimental efforts, a conclusive detection of 1D anyons in optical lattices has not yet been achieved.

Notwithstanding, from a theoretical point of view, anyons in one dimension have received continuous and legitimate interest on account of their intriguing physical properties. The exact solution of an 1D anyon gas with delta-function potential has been obtained by a Bethe ansatz technique [10]. Boundary conformal field theory shows that non-Abelian anyons may form topological insulating phases in spin-1/2 $su(2)_k$ chains [11]. For the Abelian 1D anyon-Hubbard model (AHM), the possibility of a statistically induced quantum phase transition between Mott-insulator (MI) and superfluid phases [7] and the asymmetry of the momentum distribution for hard-core [13] and soft-core anyons [14] have been addressed so far. Since the AHM is equivalent to a variant of the Bose-Hubbard model (BHM) with state-dependent bosonic hopping amplitudes [7], the next very interesting question might be whether the symmetry-protected topological (SPT) Haldane state [15, 16], observed in the extended BHM (EBHM) with an additional nearest-neighbor particle repulsion [17, 18], also shows up in the extended AHM (EAHM). Because of its SPT order, the Haldane phase in the EBHM is separated from the topologically trivial MI phase by a phase transition, as long as the protecting symmetry—being a combination of bond-centered inversion and a local unitary transformation—keeps up [16]. By breaking this symmetry, the two phases can be adiabatically connected without crossing a phase transition. Therefore, a sharp distinction between the two phases is only possible in the presence of the protecting symmetry, even though no spontaneous symmetry breaking occurs. As the hopping phase factor breaks the reflection parity in the system [19], naively one might expect the Haldane state to disappear in the EAHM for any finite fractional phase $\theta$. However, this will not happen if the protecting symmetry is appropriately generalized for finite $\theta$.

To comment on an anyonic topological Haldane state in one dimension, we scrutinize its protecting symmetry in the framework of the EAHM by analyzing the invariance of the density-dependent hopping amplitudes (as for the EBHM in the limit $\theta \rightarrow 0$). Calculating the generalized transfer matrices [20] from the infinite matrix-product state (iMPS) of the infinite density-matrix renormalization-group (iDMRG) [21, 23] simulations, we prove the existence of the Haldane insulator (HI) state and derive the complete ground-state phase diagram of this paradigmatic anyonic model Hamiltonian at unit filling. In order to discriminate the topological HI phase from the other, more conventional Mott and density-wave (DW) insulating phases in possible future experiments, we also determine the dynamical density...
response of the system, showing a characteristic asymmetry in the Brillouin zone, which can be attributed to the fractional phase factor of the anyons.

The Hamiltonian of the 1D EAHM consists of three terms, $\hat{H}_{\text{EAHM}}^{(a)} \equiv \hat{H}_t + \hat{H}_U + \hat{H}_V$, with
\[
\hat{H}_t = -t \sum_j \left( \hat{a}_j^\dagger \hat{a}_{j+1} + \text{H.c.} \right),
\]
\[
\hat{H}_U = U \sum_j \hat{n}_j (\hat{n}_j - 1)/2 \quad \text{and} \quad \hat{H}_V = V \sum_j \hat{n}_j \hat{n}_{j+1},
\]
where the nearest-neighbor anyon transfer (\(\propto t\)), as well as the repulsive on-site (\(\propto U\)) and nearest-neighbor (\(\propto V\)) particle interaction, respectively. The anyon creation ($\hat{a}_j^\dagger$), annihilation ($\hat{a}_j$) and particle number ($\hat{n}_j = \hat{a}_j^\dagger \hat{a}_j$) operators at lattice site \(j\) are defined by the generalized commutation relations [7, 10]:
\[
\hat{a}_j \hat{a}_k - e^{i\theta} \hat{a}_k \hat{a}_j = \delta_{jk},
\]
\[
\hat{a}_j \hat{a}_k - e^{i\theta} \hat{a}_k \hat{a}_j = 0,
\]
where the sign function 
\(\text{sgn}(j - \ell) = 0\) for \(j = \ell\) is mandatory, since two anyons on the same site behave as ordinary bosons. Anyons with \(\theta = \pi\) represent so-called “pseudofermions”, namely, they are fermions off-site, while being bosons on-site.

Performing a fractional Jordan-Wigner transformation [7],
\[
\hat{a}_j = \hat{b}_j e^{\theta \sum_{\ell=1}^{j-1} \hat{a}_\ell},
\]
where \(\hat{b}_j^\dagger \hat{b}_j\) is a boson creation (annihilation) operator, $\hat{H}_{\text{EAHM}}^{(a)}$ becomes $\hat{H}_{\text{EAHM}}^{(b)}$ with density-dependent hopping amplitudes,
\[
\hat{H}_t = -t \sum_j \left( \hat{b}_j^\dagger \hat{b}_{j+1} e^{i\theta \hat{n}_j} + e^{-i\theta \hat{n}_j} \hat{b}_{j+1}^\dagger \hat{b}_j \right).
\]
That is when a boson hops to the left from site \(j + 1\) to site \(j\) it acquires an occupation dependent phase $e^{i\theta \hat{n}_j}$. Of course, $\hat{n}_j = \hat{a}_j^\dagger \hat{a}_j = \hat{b}_j^\dagger \hat{b}_j$ which means that $\hat{H}_t$ and $\hat{H}_V$ are form invariant under the anyon-boson mapping [1].

If we limit the maximum number of particles per site as \(n_p = 2\), the EBHM, resulting in the limit \(\theta \to 0\) from $\hat{H}_{\text{EAHM}}^{(b)}$, maps to an effective XXZ spin-1 chain [15]:
\[
H_{\text{eff}} = -t \sum_j \left( \hat{S}_j^+ \hat{S}_{j+1}^+ + \text{H.c.} \right) + U \sum_j \left( \hat{S}_j^z \right)^2 + V \sum_j \hat{S}_j^z \hat{S}_{j+1}^z
\]
with the pseudospin operator $\hat{S}_j^z = \hat{n}_j - 1$. Here we have neglected terms that break the particle-hole symmetry. We note the negative sign of the first term compared to the usual XXZ spin-chain Hamiltonian. This leads to a protecting modified inversion symmetry $\mathcal{I}'$ for the Haldane state of the EBHM [16]:
\[
\mathcal{I}' = e^{i\pi \sum_j \hat{S}_j^z} \mathcal{I} = e^{i\pi \sum_j (\hat{n}_j - 1)} \mathcal{I}.
\]
Owing to the occupation-dependent hopping in (5), the HI phase in the EAHM seems not be protected by the modified inversion symmetry $\mathcal{I}'$.

To clarify whether $\hat{H}_t$ is invariant under certain symmetry operations, let us first consider the inversion symmetry operator $\mathcal{I}$, acting on $\hat{H}_t \to \hat{H}_t' = \mathcal{I} \hat{H}_t \mathcal{I}^\dagger$ with
\[
\hat{H}_t' = -t \sum_j \left( \hat{b}_{j+1}^\dagger \hat{b}_j e^{i\theta \hat{n}_j} + e^{-i\theta \hat{n}_j} \hat{b}_j^\dagger \hat{b}_{j+1} \right).
\]
Applying next a time-reversal transformation $\mathcal{T}$, $\hat{H}_t' \to \hat{H}_t'' = \mathcal{T} \hat{H}_t' \mathcal{T}^\dagger$, we obtain
\[
\hat{H}_t'' = -t \sum_j \left( \hat{b}_{j+1}^\dagger \hat{b}_j e^{-i\theta \hat{n}_j} + e^{i\theta \hat{n}_j} \hat{b}_j^\dagger \hat{b}_{j+1} \right).
\]
To see that $\hat{H}_t$ stays invariant under the combined symmetry operations, we make the following transformation:
\[
\hat{b}_j^\dagger \to e^{i\theta \hat{n}_j} (\hat{n}_j - 1)/2 \quad \text{and} \quad \hat{b}_j \to e^{-i\theta \hat{n}_j} (\hat{n}_j - 1)/2.
\]
Since the second term of Eq. (9) transforms as $e^{i\theta \hat{n}_j} \hat{b}_j^\dagger \hat{b}_j + e^{-i\theta \hat{n}_j} \hat{b}_j^\dagger \hat{b}_j$, it is equal to the first term of $\hat{H}_t$. Therefore the Hamiltonian $\hat{H}_{\text{EAHM}}^{(b)}$ is invariant under the transformation
\[
\mathcal{K} = e^{i\theta \sum_j \hat{n}_j (\hat{n}_j - 1)/2} \mathcal{I} \mathcal{T}.
\]
We now show that the combination of $\mathcal{R}_z = e^{i\pi \sum_j \hat{S}_j^z} = e^{i\pi \sum_j (\hat{n}_j - 1)}$ and $\mathcal{K}$ is related to an SPT phase in the
EAHM, and define a corresponding topological order parameter. Following Ref. [24], we use the iMPS representation formed by complex \( \chi \times \chi \) matrices \( \Gamma_\sigma \) and a positive, real, diagonal matrix \( \Lambda \):

\[
|\psi\rangle = \sum_{\ldots, \sigma_j, \sigma_{j+1}, \ldots} \Lambda^{j+1} \Gamma_{\sigma_j} \Gamma_{\sigma_{j+1}} \cdots |\ldots, \sigma_j, \sigma_{j+1}, \ldots\rangle,
\]

where the index \( \sigma \) labels the basis states of the local Hilbert spaces. The iMPS is assumed to be in the canonical form: \( \sum_\sigma \Gamma_\sigma \Lambda^\sigma \Gamma_\sigma^\dagger = \sum_\sigma \Gamma_\sigma^\dagger \Lambda^\sigma \Gamma_\sigma = 1 \). If a state \( |\psi\rangle \) is invariant under an internal symmetry that is represented by a unitary matrix \( \Sigma_{\sigma \sigma'} \), then the transformed \( \Gamma_\sigma \) matrices satisfy [16, 25]

\[
\sum_\sigma \Sigma_{\sigma \sigma'} \Gamma_{\sigma'} = e^{i\phi} U^\dagger \Gamma_\sigma U,
\]

where \( U \) is a unitary matrix that commutes with \( \Lambda \) and \( e^{i\phi} \) is a phase factor. Similar relations hold for time reversal symmetry, inversion symmetry, and a combination of both. In those cases \( \Gamma_\sigma \) on the left-hand side is replaced by its complex conjugate \( \Gamma^*_\sigma \), its transpose \( \Gamma^T_\sigma \) and its Hermitian transpose \( \Gamma^\dagger_\sigma \), respectively. The properties of the matrices \( U \) can be used to classify SPT phases [16, 26]. For instance, in the case of time reversal or (modified) inversion symmetry the matrices satisfy \( U^\dagger \Gamma^T_\sigma = \pm \Gamma^T_\sigma \parallel U^\dagger \Gamma^\dagger_\sigma = \pm \Gamma^\dagger_\sigma \)), and the sign distinguishes between two symmetric phases. In the EAHM, the situation is slightly different because time reversal and inversion are not symmetries of the system, only a combination \( K \) of them is. For \( R^z \) and \( K \) we have \( U^T_\mathcal{R} = e^{i\alpha R^z} I \) and \( U^T_K = e^{i\alpha K} I \). From this we can derive an SPT order parameter similar to the case of the \( Z_2 \times Z_2 \) spin rotation symmetry of \( R^2 \) and \( R^x \) in the spin-1 XXZ chain [16]. Since the phase factors \( e^{i\alpha R^z} \) and \( e^{i\alpha K} \) can be removed by absorbing them into the corresponding matrices \( U^T_\mathcal{R} \) and \( U^T_K \) they have no physical meaning. However, if both \( R^z \) and \( K \) are preserved, the combination \( R^z K \) is a symmetry as well and its phase factor is not arbitrary if \( U^T_\mathcal{R} \) and \( U^T_K \) have been fixed. Indeed one can show that \( U^T_\mathcal{R} U^T_K = \pm U^T_K U^T_\mathcal{R} \) which defines two different phases. To verify that the EAHM has a nontrivial topological phase protected by \( R^z \) and \( K \), we calculate the order parameter [20]

\[
O = \frac{1}{\chi} \text{tr} \left( U^T_K U^T_\mathcal{R} U^\dagger_K U^\dagger_\mathcal{R} \right),
\]

if the state is symmetric under both \( K \) and \( R^z \). Otherwise, if one of the symmetries is broken, the order parameter is zero.

The iDMRG results for the order parameter are shown in Fig. 1. If \( U^T_\mathcal{K} \) and \( U^T_\mathcal{R} \), commute \( (O = 1) \), the system is in a trivial phase, i.e., a site-factorizable MI state, whereas if they anticommute \( (O = -1) \), the system realizes a nontrivial HI state. Since the order parameter \( O \) changes its sign only if a phase transition takes place, the HI is a well-defined phase of the EAHM. Increasing

![FIG. 2. (Color online). Ground-state phase diagram of the extended anyon-Hubbard model in one dimension, where the particle density \( \rho = 1 \), \( n_p = 2 \), and \( \theta = \pi/4 \). Most notably the Haldane insulator (HI), located between Mott insulator (MI) and density wave (DW) insulating phases in the EBHM, survives for any \( \theta > 0 \), i.e., in the anyonic case. Likewise the superfluid (SF) appears in the very weak-coupling regime. The MI-HI (squares) and HI-DW (circles) transition points can be determined by a divergent correlation length \( \xi_\chi \), \( \chi \) increases, i.e., the model becomes critical with the central charge \( c = 1 \) and \( c = 1/2 \), respectively (see Ref. [27]). For comparison, the dotted (dashed) line marks the MI-HI (HI-DW) transition in the EBHM \( (\theta = 0) \) [29]. The dash-dotted line with triangles up denotes the first-order MI-DW phase transition for \( \theta = \pi \).

the number of particles per site \( n_p \) at fixed \( U/t = 5 \), the HI phase \( (O = -1) \) slightly shifts to larger value of \( V/t \) but, most notably, the Haldane phase still occupies a solid parameter region, see the data for \( n_p = 3 \) and 5 in Fig. 1a. Increasing the fractional angle \( \theta \) for \( n_p = 2 \), the Haldane state region narrows [see Fig. 1b] for \( \theta = \pi/2 \) and disappears (at least) for \( \theta = \pi \) [28]. We would like to emphasize that the HI sector marked in Fig. 1 by the gray area agrees with that extracted from the correlation length, the entanglement spectrum, and the numerically obtained central charge [27].

Figure 2 represents the ground-state phase diagram of the 1D EAHM in the \( V/U \) plane, as obtained from large-scale iDMRG calculations for \( \theta = \pi/4 \) and \( n_p = 2 \). The phase boundaries are determined simulating the order parameter \( O \), as well as the correlation length and the entanglement spectrum [27]. The EAHM exhibits three different insulating phases (MI, DW, and HI) and a superfluid state in the weak interaction regime, just as for the EBHM [29] but with the addition that the region of the intervening anyonic HI phase at \( \theta = \pi/4 \) is slightly reduced. The HI vanishes in the pseudofermionic case \( (\theta = \pi) \). According to field theory for the EBHM [18, 30], which is based on the bosonization procedure developed for integer-spin chains [31, 32], the MI-HI and HI-DW
quantum phase transitions belong to the universality class of Tomonaga-Luttinger liquid and Ising model, with central charge $c = 1$ and $1/2$, respectively, see Fig. S1(c) in [27]. That is the universality classes are not modified by the fractional angle.

Perhaps the most striking feature of the AHM is the asymmetry of the momentum distribution function in $k$-space [19][14]. The position of the maximum strongly depends on the fractional phase $\theta$ [remind that the momentum distribution diverges at $k = 0$ in the BHM ($\theta = 0$)]. We expect that this asymmetry can also be observed in dynamical quantities such as the dynamical structure factor $S(k, \omega)$. Hence, if an anyonic system will be realized in optical lattices, $S(k, \omega)$ might be one of the best physical quantities to look at, comparing theoretical predictions with real experiments, like for 1D Bose–Hubbard type models [33]. $S(k, \omega)$ should be easily accessible by momentum resolved Bragg spectroscopy [31]. Furthermore, it has been recently demonstrated that $S(k, \omega)$ can also be used to distinguish the topological HI from the conventional MI and DW states [29][35], in analogy to exploiting the dynamical spin-spin structure factor in the spin-1 XXZ chain [30].

The dynamical density structure factor is defined as

$$S(k, \omega) = \sum_{n} \langle \langle \psi_n | \hat{n}_k | \psi_n \rangle \rangle^2 \delta(\omega - \omega_n),$$

where $|\psi_0\rangle (|\psi_n\rangle)$ denotes the ground ($n$th excited) state, and $\omega_n = E_n - E_0$. To compute this quantity, we follow Ref. [37] and first determine the two-point correlation function $\langle \psi_0 | \hat{n}_j (\tau) \hat{n}_0 (0) | \psi_0 \rangle$ by real-time evolution of the iMPS $|\psi_0\rangle$. Fourier transformation then provides us with accurate numerical results of the dynamical structure factor in the EAHM.

Figure 3 compares the intensity of the dynamical wave-vector-resolved density response in the EBHM ($\theta = 0$) with those in the EAHM for $\theta = \pi/4$, for $U/t = 5$, at five characteristic $V/t$-values. One point worthy of remark is that each of the phases and phase transitions can be distinguished by looking at $S(k, \omega)$. In the MI, at $V = t$ [Figs. 3(a) and 3(f)], the excitation gap appears at $k \approx 0$. With increasing $V/t$, the MI-HI transition occurs at $V \approx V_{c1}$, where the excitation gap closes at $k = 0$, as shown in Figs. 3(b) and 3(g). Deep in the HI phase, $V = 3t$ [Figs. 3(c) and 3(h)], the spectral weight exclusively concentrates at $k \approx \pi$, and there are finite excitation gaps at $k = 0$ and $\pi$. It is of particular interest to see whether the gap $S(k, \omega)$ closes at the HI-DW transition point. Indeed, the excitation gap at $V = V_{c2}$ closes, but at momentum $k = \pi$, reflecting the lattice-period doubling in the DW phase. Moreover, in the DW phase [Figs. 3(e) and 3(j)], we find a large excitation gap at $k = \pi$ and two dispersive branches, where a changeover of the intensity maximum occurs at $k = \pi/2$ ($k = 3\pi/4$) for $\theta = 0$ ($\theta = \pi/4$). Interestingly, the influence of the occupation-dependent phase of $H_L$ in Eq. (5) shows up in $S(k, \omega)$ as well, which helps to differentiate the results from those of the EBHM. $S(k, \omega)$ of the EAHM is asymmetric for any $0 < \theta < \pi$, while $S(k, \omega)$ in the EBHM is always symmetric about $k = \pi$.

To summarize, we carried out an unbiased numerical investigation of the extended anyon-Hubbard model in one dimension and determined its ground-state phase diagram with high precision exploiting the behavior of correlation lengths and entanglement spectra. Defining an order parameter that distinguishes trivial and nontrivial topological phases, we were able to show that the EAHM possesses an anyonic Haldane insulator state sandwiched between superfluid, Mott insulator and density-wave phases. Both the HI-MI and HI-DW quantum phase transitions are critical with central charge 1 and $1/2$, respectively. While the HI state survives the EBHM limit
(θ = 0), it vanishes when the system is composed of pseudofermions (θ = π). If a 1D interacting anyonic system could be realized experimentally in the future, maybe in an optical-lattice setup with ultracold atoms, we suggest performing momentum-resolved Bragg spectroscopy to look for the pronounced asymmetry of the density response spectra in momentum space that we have demonstrated in our model calculation theoretically.

[27] See Supplementary material for further quantities to determine and characterize the phase boundaries and quantum phase transitions.
[28] Note that our iDMRG scheme holds for arbitrary θ. Additional iDMRG calculations confirm that the HI phase exists not only for the specific fractional angles θ used in Fig. 1 but also for other values of θ ∈ (0, π) (not shown). The critical θc, where the HI phase disappears, depends on the model parameters U, V, and np.
Supplementary material

As discussed in the main text, we find compelling evidence for the existence of the symmetry-protected topological Haldane insulator phase in the one-dimensional (1D) extended anyon-Hubbard model (EAHM), by calculating an order parameter from the largest eigenvalues of the generalized transfer matrix within an infinite density-matrix renormalization group (iDMRG) scheme.

Here we show that for the EAHM (with maximum number of particles per site \( n_p = 2 \)) further quantities can be exploited in order to determine and characterize the phase boundaries and quantum phase transitions with high precision.

The entanglement analysis in particular provides us with valuable information about the existence of a symmetry protected Haldane insulator (HI) in the EAHM. Furthermore, it allows to determine the phase boundaries between the HI and other insulating phases. Dividing a system into two subblocks, \( \mathcal{H} = \mathcal{H}_L \otimes \mathcal{H}_R \), and considering the reduced density matrix \( \rho_L = \text{Tr}_R[\rho] \), the entanglement spectra [S1] can be extracted from the singular values \( \lambda_\alpha \) as \( \epsilon_\alpha = -2\ln \lambda_\alpha \). In addition, the correlation length \( \xi_\chi \) can be obtained from the second largest eigenvalue of the transfer matrix for some fixed bond dimension \( \chi \) in an iDMRG simulation [S2, S3]. While \( \xi_\chi \) stays finite as a consequence of the fixed bond dimension \( \chi \), the physical correlation length will diverge at the critical point. Nevertheless, \( \xi_\chi \) is useful to pinpoint a phase boundary because it rapidly increases with \( \chi \) close to the quantum phase transition point, see also Ref. [S5] for the corresponding discussion in the AKLT model [S6].

Figures S1(a) and (b) show \( \xi_\chi \) and \( \epsilon_\alpha \) as functions of \( V/t \) for fixed \( U/t = 5 \). The strong upturn of \( \xi_\chi \) indicates the formation of a HI phase in the EAHM for \( \theta > 0 \). We find distinct peaks at \( V_{c_1} \approx 2.859\theta \) and \( V_{c_2} \approx 3.255\theta \), which become more pronounced as \( \chi \) grows from 100 to 200, signaling a divergence of \( \xi_\chi \rightarrow \infty \) as \( \chi \rightarrow \infty \). At the same time, the entanglement spectra develops a characteristic double degeneracy in all entanglement levels for \( V_{c_1} < V < V_{c_2} \), indicating a symmetry-protected topological phase between MI and DW states.

The universality class of these quantum phase transitions can be explored by calculating the central charge numerically, just as in case of the EBHM [S5]. When the system gets critical the central charge can be determined very accurately by DMRG, utilizing the relation [S7]

\[
\frac{c^*(L)}{\ln[\cos(\pi/L)]} = \frac{3[S_L(L/2 - 1) - S_L(L/2)]}{\ln[\cos(\pi/L)]}.
\]

In this way, the MI-SF transition in the BHM [S8], and especially, the universality class of the MI-HI and HI-DW quantum phase transitions in the EAHM have been determined in the past [S5].

Figure S1(c) displays \( c^*(L) \) for the 1D EAHM, where the model parameters are the same as in Figs. S1(a) and (b). Running the DMRG we adopt periodic boundary conditions for system sizes up to \( L = 64 \). For \( U/t = 5 \) and \( V \lesssim V_{c_1} \) [\( V \approx V_{c_2} \)], we find \( c^*(L = 64) \approx 0.996 \) [\( c^*(L = 64) \approx 0.494 \)], which points to the universality class of the Luttinger liquid (Ising) model, in accordance with what was obtained for the corresponding quantum phase transitions in the EBHM (\( \theta = 0 \)).
