(December 25, 2021)

The decay rates of the density-density correlation function are computed for a chaotic billiard with some amount of disorder inside. In the case of the clean system the rates are zeros of Ruelle’s Zeta function and in the limit of strong disorder they are roots of Selberg’s Zeta function. We constructed the interpolation formula between two limiting Zeta functions by analogy with the case of the integrable billiards. The almost clean limit is discussed in some detail.

PACS numbers: 05.20.Dd, 05.45.+b, 51.10.+y

It is natural to assume that chaotic billiards with a small amount of disorder are good models for ballistic cavities which have been employed in a number of recent experiments, see Refs. 1–3. Such a model is interesting because the disorder (in two dimensions) can be characterized by one parameter: the elastic scattering time \( \tau \). The mixing properties of this model in two important limits \( \tau \to 0 \) and \( \tau \to \infty \) were known in the literature, see Refs. 4, 5, 6. In the present work we discuss the crossover from one limit to the other for some two-dimensional billiard. The case of the three-dimensional billiards is more complicated. Particularly, the uniform scattering in three dimensions leads to very fast resonant mixing. At the end of the paper we provide the generalization of our results for the case of three dimensions.

Let us focus attention on the eigenvalues and the eigenmodes of the kinetic equation for the distribution function \( f(\vec{r}, \phi) \) of non-interacting particles inside a two-dimensional billiard. This function is defined on the constant energy manifold \( |\vec{v}_\phi| = v = \text{const} \), and \( \vec{v}_\phi = (v \cos(\phi), v \sin(\phi)) \). The precise form of the kinetic equation depends on the details of the impurity potential, but we are going to investigate two models

\[
\frac{\partial f}{\partial t} + \vec{v}_\phi \nabla f = \begin{cases} \frac{\partial f}{\partial t} + \frac{1}{\tau} \vec{v}_\phi \nabla f, & \text{model 1} \\ \frac{\partial f}{\partial t} + \frac{1}{\tau} \frac{\partial f}{\partial \phi}, & \text{model 2} \end{cases},
\]

where \( \tilde{f}(\vec{r}) = \int f(\vec{r}, \phi) d\phi/(2\pi) \). The above equation has to be solved with mirror boundary conditions \( f(\vec{r}^\prime, \phi) = f(\vec{r}^\prime, 2\alpha(\vec{r}^\prime) - \pi - \phi) \), where \( \vec{r}^\prime \) is taken on the boundary of the billiard and \( \alpha = (\cos(\alpha), \sin(\alpha)) \) is normal to the boundary. Equation (1) has a special solution \( f_0(\vec{r}, \phi) = \text{const} \) for all values of \( \tau \) and we will ignore it in the rest of the paper.

In both models, the collision integral conserves energy. The first model corresponds to uniform scattering in all directions and the second model is valid if small angle scattering is dominant. Let us look for solutions proportional to \( e^{-s_n \tau} \). The eigenvalues \( s_n \) of the kinetic equation are so-called mixing rates, or decay rates of the density-density correlation function when \( \tau \to 0 \) or Ruelle’s resonances when \( \tau \to \infty \).

These resonances can be found as zeros of the spectral determinant \( Z(s) \). Let us start to compute \( Z(s) \) in the limit of pure chaos. Cvitanovic and Eckhardt have computed the spectral determinant for the axiom A system, but the result is the expansion over the unstable periodic orbits and it seems to be valid for wide class of systems. Therefore in the limit \( \tau \to \infty \) the spectral determinant is

\[
-\log(Z(s)) = \sum_{p=1}^{\infty} \frac{1}{r} \frac{1}{|\det(I - M_p)|} e^{s_{pr}/v},
\]

where \( v \) is the velocity. This expression contains the sum over the primitive periodic orbits \( p \) taken with repetition \( r \). In the case of billiards, the action for the periodic trajectory is just the length \( l_p \). Each oscillating term in the sum in Eq. (3) is weighted by the stability amplitude which behaves on average as

\[
\frac{1}{|\det(I - M_p)|} \approx e^{-\lambda_{pr} l_p/v} \approx e^{-\lambda_{pr}/v},
\]

where the first equality defines \( \lambda_{pr} \), and \( \lambda \) is the Lyapunov exponent of the billiard. The Zeta function given by Eq. (3) is of Ruelle’s type.

When the disorder is strong, the kinetic equation can be transformed into the diffusion equation for \( \tilde{f} \)

\[
\frac{\partial \tilde{f}}{\partial t} - \frac{\alpha^2 \tau}{2} \nabla^2 \tilde{f} = 0,
\]

which has to be solved with boundary conditions \( \tilde{n} \nabla \tilde{f} = 0 \). This equation allows one to find the decay of modes with \( \tilde{f} \neq 0 \). The decay rates for modes with \( \tilde{f} = 0 \) for all \( \vec{r} \) should be computed in a different way.

In the limit \( \tau \to 0 \) we can use the “semiclassical” approximation for equation

\[
(k^2 + \nabla^2) \tilde{f} = 0,
\]
where \( k^2 = 2s/(\nu^2 \tau) \). The logarithm of the Selberg’s type Zeta function is again the sum over periodic orbits:

\[
- \log(Z(s)) = \sum_{p} \frac{1}{\tau} \frac{1}{\sqrt{\det(I - M_{\tau}^p)}} e^{ikl_{p}r} .
\] (6)

Here the phase factors correspond to the case when Eq. (2) should be solved with the Neumann boundary condition and Maslov’s indexes vanish.\(^4\) The natural question to ask is whether it is possible to compute the decay rates of the modes with \( f \neq 0 \) for all values of \( \tau \) by constructing a suitable Zeta function?

We can understand the connection between different types of Zeta functions by making use of the following approximation

\[
- \log(A(x)) \equiv \sum_{p} e^{\tau l_{p}}
\] (7)

\[
Z(s) \approx A\left(\frac{s - \lambda}{\nu}\right) \quad \tau \to \infty
\] (8)

\[
Z(s) \approx A(i\sqrt{\frac{2s}{\nu^2 \tau} - \frac{\lambda}{2\nu^2}}) \quad \tau \to 0
\] (9)

where we have neglected the repetitions of periodic orbits and fluctuations of the Lyapunov exponent in Eqs. (8) and (9). Let us denote the eigenvalues of the wavenumber in Eq. (8) as \( q_n, n = 1 \ldots \infty \). We therefore suggest that eigenvalues of the kinetic equation are

\[
s_n = \left\{ \begin{array}{l}
q_n^2 \frac{v^2 \tau}{2} + \frac{\lambda}{2} + iq_n v \\
\frac{\lambda}{2} + iq_n v
\end{array} \right. \quad \tau \to 0, \quad \tau \to \infty,
\] (10)

where \( \lambda \) is the mean Lyapunov exponent. In order to obtain the second expression we have noted that the function \( A(x) \) should have zeros \( x_n = iq_n - \frac{\lambda}{2\nu} \) and we have made use of Eq. (8). We would like to emphasize that Eq. (10) has nothing to do with the convergence properties of the Zeta functions. It based on the fact that Ruelle’s type Zeta function Eq. (8) and Selberg’s type Zeta function are almost the same function \( A(x) \) taken with different arguments. The second case in Eq. (10) means that there is a shift of \( \lambda/2 \) between the zeros of Ruelle’s type Zeta function and the zeros of Selberg’s type Zeta function. Such a shift was observed in the problem of quantum and classical scattering in a three disk problem, compare Figs. 2.14 and 3.6 of Ref. [11] and see Refs. [12],[13] for details. The main idea of this work is to obtain known Zeta functions as the two limits of one kinetic Zeta function.

Let’s examine first the integrable case. Model 1 for the square billiard was solved by Atland and Gefen\(^6\) and Agam and Fishman\(^4\), who modeled the short range random potential by random spheres or circles. For the square billiard of size \( L \) the spatial dependence of the density \( f(r) \) is \( \sum \exp(i\bar{q} \cdot \bar{r}) \), where \( q \) is such that \( \sin(q_x L) \sin(q_y L) = 0 \), and the sum is over four possible directions of \( \bar{q} \). Then the values of \( q \) are “quantized”, and we will denote them \( q_n \), and the modes with \( f \neq 0 \) can be numbered

\[
f_n(\bar{r}, \phi, t) \propto \sum_{s} \frac{\tau^{-1}}{-s + \tau^{-1} + i\bar{q}_n \bar{r}} \propto \sum_{s} e^{i\bar{q}_n \bar{r} - st} ,
\] (11)

where the sum is over four possible directions of \( \bar{q}_n \). Integration over \( \phi \) leads to the equation for \( s_n \)

\[
\tau^{-2} = (s_n - \tau^{-1})^2 + v^2 \frac{q_n^2}{\nu^2} ,
\] (12)

and the corresponding Zeta function is

\[
- \log(Z(s)) = \sum_{p} \frac{L_1^2 q_n^2}{\pi^2 q_{\nu}^2} e^{i\bar{q}_{\nu} \bar{r}} ,
\] (13)

where \( p \) is not a single orbit but the resonant torus\(^3\), and the connection between \( s \) and \( q \) is as in Eq. (12).

In the case of model 2, the solutions are still proportional to \( e^{i\bar{q} \cdot \bar{r}} \), but the angular dependence is different. The solution with \( f \neq 0 \) is the “ground state” of

\[
\left[-s + i\bar{q} \times \bar{q} - \frac{1}{\tau} \frac{\partial^2}{\partial \phi^2}\right] f_n = 0,
\] (14)
because the real parts of the decay rates are positive. Surprisingly, Eq. (12) gives a numerically good approximation for $s_n$ for this model. Other “angular” modes, which have $f \neq 0$, are very different for models 1 and 2.

It is not easy to compute eigenmodes of Eq. (1) for the integrable billiards which have other than rectangular shapes. For such cases Eq. (13) becomes an interpolation formula for the kinetic Zeta function. One should only replace the pre-exponential factor by the amplitude from the Berry – Tabor formula. For example, the resonant tori for the circular billiard of radius $R$ are numbered by the winding number $M$ and by the number of vertices $n$, have length $l_{MN} = nL_{MN}/\pi$, where $L_{MN} = 2\pi R \sin(\pi M/n)$. Then one can use Eq. (13) after the replacement $p \to M_{n}$, and $L \to L_{M_{n}}$, see Ref. 16.

Combining together Eqs. (3), (1), (2), and (13) we can introduce the kinetic Zeta function as

$$-\log(Z(s)) = \sum_{p} \sum_{r=1}^{\infty} \frac{1}{r} \frac{1}{r^2 - \tau_{pr}^2} \times \log(\lambda \tau_{pr}^2/2|l_{pr}/v|),$$

(15a)

where

$$\tau_{pr} = \begin{cases} \tau, & \frac{\lambda \tau_{pr}^2}{2} < 1 \\ 2/\lambda \tau_{pr}, & \frac{\lambda \tau_{pr}^2}{2} > 1 \end{cases}.$$  

(15b)

For $\lambda \tau < 1/2$ the kinetic Zeta function coincides with Selberg’s type Zeta function Eq. (1) in the domain of the complex s plane $|s| < 1$. For $\lambda \tau > 1/2$ the kinetic Zeta function becomes independent of $\tau$ and coincides with Ruelle’s type Zeta function Eq. (2) in the domain of the complex s plane $|s| > 1$.

The interpolation formula Eqs. (13) for the kinetic Zeta function implies the following interpolation formula for the decay rates

$$s_n = \begin{cases} \frac{1}{\tau} - \sqrt{\frac{1}{\tau^2} - \left(\frac{q_n}{v}\right)^2}, & \frac{1}{q_n} \geq \tau \\ \frac{1}{\lambda \tau} + i\left(\frac{q_n}{v}\right)^2 - \frac{1}{\tau^2}, & \frac{2}{\lambda} \geq \tau \geq \frac{1}{q_n}, v \\ \frac{2}{\lambda}, & \tau \geq \frac{2}{\lambda} \end{cases}$$

(16)

where $q_n$ are the eigenvalues of the wavenumber in Eq. (2). There is a gap between the last two expressions $s_n|_{\tau^2=2/\lambda} - s_n|_{\tau^2=2/\lambda+0} \sim \lambda^2/(q_n v)$, which is numerically small for most cases. The motion of the decay rates on the complex plane is schematically shown in Fig. 4.

In the limit of strong disorder some of the $s_n$ are on the real axis, and the imaginary part of $s_n$ becomes non-zero when $\tau q_n v = 1$. Then $s_n$ moves along the arc and stops when $\tau = \lambda/2$.

Equations (10) and (16) show that a chaotic system is qualitatively different from a diffusive system from the point of view of the position of Ruelle’s resonances $s_n$ on the complex plane. In the chaotic limit all resonances lie on a line parallel to the imaginary axis. The disorder induces motion of the resonances toward the real axis as was found by Agam and Fishman.

The interpolation formula between Ruelle’s type and Selberg’s type Zeta exists only if the diffusion modes transform to the so-called Frobenius – Perron modes as the disorder goes to zero. This has not yet been proven for our case. The main difficulty is that the diffusion modes are selected from all kinetic modes by the condition $f \neq 0$. At the same time Frobenius-Perron modes are selected by the choice of the functional space. However, in other systems one can consider the diffusion modes as modes of the Frobenius – Perron operator.

Some additional information might be obtained from the properties of the propagator of Eq. (1), which can be written as a path integral for model 2

$$G(\vec{r}, \phi, \vec{r}_0, \phi_0, t) = \int D[\vec{v}]e^{i(\vec{r} - \vec{r}_0 - \int_0^t \vec{v} \cdot dt)}$$

$$\times e^{-\frac{1}{2} \int_0^t \dot{\vec{v}}^2 dt + \int_0^t \dot{\vec{v}} \cdot \vec{v} dt + \ldots + \int_0^t \ddot{\vec{v}} \cdot \vec{v} dt}$$

(17)

where $\psi(0) = \phi_0$, $\psi(t_j - 0) + \psi(t_j + 0) = 2\alpha_j$, ..., $\psi(t) = \phi$, and the path $\vec{r}_0 + \int_0^t \vec{v} \cdot dt$ touches the boundaries $n$ times at the points $\vec{r}_1, \ldots, \vec{r}_n$, at the times $t_1, \ldots, t_n$. The angle $\alpha_j$ is the direction of the tangent to the boundary at the reflection point $\vec{r}_j$. The trace of the propagator Eq. (17) known also as the return probability is

$$p(t) = \int d\vec{r}_0 \int d\phi \int D[\psi] e^{-\frac{1}{2} \int_0^t \dot{\vec{v}}^2 dt} \delta(\int_0^t \vec{v} \cdot dt),$$

(18)

where $\psi(t) = \psi(0) = \phi$ and $\int_0^t \vec{v} \cdot dt$ is defined as in Eq. (17).

The propagator Eq. (13) should interpolate between the Frobenius – Perron operator in the limit $\tau \to \infty$ and the diffusion operator in the limit $\tau \to 0$. Then the trace of this propagator Eq. (13) should provide us with a systematic way to compute the interpolation formula for the Zeta function, because $-\log Z(s) = \int_0^\infty e^{st} t^{-1} p(t) dt$. Here the sign of $st$ in the Laplace transform is positive, because we want the roots of the Zeta function to have the meaning of the decay rates.

In the limit of weak disorder $\tau \to \infty$, one may hope to obtain the small corrections $\propto \frac{1}{\tau}$ to the Frobenius – Perron operator, and therefore to Eq. (2). Particularly one may expect to obtain the additional “stabilization” of the periodic orbits through the disorder. Let’s consider the vicinity of the periodic orbit $p$ in phase space. The path in such a vicinity can be described by the coordinate $x(t) = vt$ along the orbit, by the coordinate $y(t)$ normal to the orbit, and by the deviation of the direction of motion $\phi(t)$. The position of the particle at the end of the path and at the beginning of the path are connected by

$$y(t) = M_p \left(y(0) + \sum_{j=1}^{n_p} M_{pj} \left(\frac{\theta_j L_{pi}}{\theta_j}ight)\right),$$

(19)
where the orbit $p$ crosses the billiard $n_p$ times. In other words the orbit consists of $n_p$ segments of length $L_{pj}$. When the particle is going along the segment $j$, it can be scattered by the disorder at small angle $\theta_j$, and then the rest of the path is distorted too. The cumulative change of the end of the path is given by the sum in the right hand side of Eq. (19), where $M_{pj}$ is the monodromy matrix of the piece of the orbit consisting of the segments $L_{pj+1}, \ldots, L_{pm}$, One can see immediately from Eq. (19), that the stability amplitude of the closed path $y(t) = y(0), \phi(t) = \phi(0)$ is independent of $\theta_1, \ldots, \theta_{n_p}$, and therefore it is independent of $\tau$. Therefore, there are no $1/\tau$ corrections to the Zeta function Eq. (2) and our interpolation formula Eq. (15) is independent of $\tau$ for $\tau > 2/\lambda$.

In the case of the three dimensional billiards the effect of the disorder is different because the scattering becomes three-dimensional and the distribution function depends on the three coordinates and two angles. For the cubic billiard the spatial dependence of the density is again $\sum e^{i\vec{q}\vec{r}}$, where the sum is over the six orthogonal orientations of $\vec{q}$, and the modes are selected by the rule $\sin(q_x L) \sin(q_y L) \sin(q_z L) = 0$. Then, the dispersion relation for the analog of model 1, (uniform scattering), can be found in Ref. [13]:

$$1 - \nu = \frac{qv\tau}{\tan(qv\tau)}, \quad (20)$$

where $qv\tau < \pi$. In other words there are no modes with $qv\tau \geq \pi$, and $\bar{f} \neq 0$, where the bar means the average over the solid angle. Equation (24) describes the diffusion modes for small $\tau$, but it cannot be used for large $\tau$. If the mode has $q$ close to $\pi/(qv\tau)$ then the decay of such a mode is very fast $s \propto (\pi - qv\tau)^{-1}$.

The model with small angle scattering in three dimensions is the Fokker–Planck equation for the distribution function, which should be solved together with mirror boundary conditions on the billiard boundary. The solutions inside the cubic billiard have the same dispersion $s(q)$ as in the case of the square billiard, if $\bar{f} \neq 0$. Therefore one may hope that Eq. (13) gives the interpolation of the Zeta function of the Fokker–Planck equation for modes with $\bar{f} \neq 0$.

In summary, we have constructed the interpolation formula for the Zeta function of the kinetic equation, in both “chaotic”, Eqs. (13), and “integrable”, Eq. (13) cases. From the mathematical point of view our kinetic Zeta function interpolates between Ruelle’s and Selberg’s Zeta functions. Our formulas are independent of the particular choice of the collision integral for two-dimensional billiards and are suitable for small angle scattering in three dimensions.
