(Dated: October 6, 2016)

We investigate the effects of magnetic inhomogeneities and thermal fluctuations on the magnetic properties of a rare earth intermetallic compound, Nd$_2$Fe$_{14}$B. The constrained Monte Carlo method is applied to a Nd$_2$Fe$_{14}$B bulk system to realize the experimentally observed spin reorientation and magnetic anisotropy constants $K_m^A$ ($m = 1, 2, 4$) at finite temperatures. Subsequently, it is found that the temperature dependence of $K_m^A$ deviates from the Callen–Callen law, $K_m^A(T) \propto M(T)^3$, even above room temperature, $T_R \sim 300$ K, when the Fe (Nd) anisotropy terms are removed to leave only the Nd (Fe) anisotropy terms. This is because the exchange couplings between Nd moments and Fe spins are much smaller than those between Fe spins. It is also found that the exponent $n$ in the external magnetic field $H_{ext}$ response of barrier height $F_R = F_R^0(1 - H_{ext}/H_R)^n$ is less than 2 in the low-temperature region below $T_R$, whereas $n$ approaches 2 when $T > T_R$, indicating the presence of Stoner–Wohlfarth-type magnetization rotation. This reflects the fact that the magnetic anisotropy is mainly governed by the $K_m^A$ term in the $T > T_R$ region.

I. INTRODUCTION

Rare earth permanent magnets, particularly Nd-Fe-B, exhibiting strong magnetic performance and attracting considerable attention because of the rapidly growing interest in electric vehicles. The main focus of research in involving these materials is to increase the coercive field $H_c$ and improve the temperature dependence $2,3$. Therefore, a number of studies have conducted micromagnetic simulations $2,3,6$ for the magnetization processes using inhomogeneous magnetic parameters to describe the complex structures in sintered magnets. Many of the results predict that the distinctive feature of magnetic anisotropy near the grain boundaries of Nd-Fe-B particles is responsible for the degradation of $H_c$.

Thus, one of the remaining subjects of the theoretical study is to give quantitative aspects in microscopic viewpoint or in atomic-scale, to the $m$-th order magnetic anisotropy constants $K_m^A$ and their temperature dependence near the grain surfaces or grain boundaries. For $K_1^A$ at the surface of Nd-Fe-B particles, Moriya et al. $11$ and Tanaka et al. $12$ calculated the crystal field parameter $A_0^1$ using a first-principles technique and pointed out that $K_1^A$ (mainly proportional to $A_0^1$) is negative at the (001) surface when the (001) Nd layer is exposed to a vacuum. However, few theoretical studies have examined the temperature dependence of $K_m^A$, even for the bulk system, since the qualitative theory was developed by Callen and Callen $13,14$. Recently, Sasaki et al. $16,17$ and Miura et al. $18$ conducted theoretical studies in the quantitative level on the temperature dependence of $K_m^A$ for a Nd$_2$Fe$_{14}$B bulk system based on crystal field theory, and successfully reproduced various experimental results. However, as these theories relied on the mean field approach in terms of the exchange coupling between the Nd $4f$ moments and Fe $3d$ spins, the results cannot be directly applied to $K_m^A$ near the surfaces or interfaces of particles. Moreover, because the crystal field analysis employed in these works is based on a quantum mechanical approach, which is typical for $4f$ electronic systems $16$, it is effectively impossible to treat finite systems of nm- or µm-scale using a similar method.

Therefore, in the present work, in anticipation of future work on magnetization reversal in finite-sized particles, we employed a realistic model with a classical Heisenberg Hamiltonian to calculate the magnetic properties of a Nd$_2$Fe$_{14}$B bulk system at finite temperatures. The key features of our model are: 1) an appropriate crystalline electric field Hamiltonian $19$ is included in the classical manner, 2) exchange coupling parameters are obtained by first-principles calculations, 3) $K_m^A$ is directly evaluated from Monte Carlo (MC) simulations without employing the mean field analysis, and 4) the constrained Monte Carlo (C-MC) method $20$ is adopted to evaluate the temperature dependence of magnetic anisotropy. Note that we can naturally realize the experimentally observed spin reorientation and $K_m^A$. Referring the (inhomogeneous) variation of magnetic parameters in the unit cell composed of 68 atoms (see Fig. 1), $K_1^A$ does not obey the Callen–Callen law $13,14$ which states that $K_1^A(T) \propto M(T)^3$ when considering only the Nd (Fe) anisotropy terms and neglecting the Fe...
(Nd) anisotropy terms. We also analyze the response of the external magnetic field \( H_{\text{ext}} \) for a barrier height \( \mathcal{F}_B(H_{\text{ext}}) = \mathcal{F}_B^0(1 - H_{\text{ext}}/H_0)^n \), and find that the \( H_{\text{ext}} \) response deviates from the Stoner–Wohlfarth-type \( n = 2 \), especially below room temperature, \( T_R \sim 300 \text{ K} \).

II. MODEL AND METHOD

A. Model

By treating each atom as having classical spin, we constructed a three-dimensional Heisenberg model including realistic atom locations for Nd\(_{2}\)Fe\(_{14}\)B, as shown in Fig. 1. This model using atomic-scale parameters was defined as follow:

\[
\mathcal{H} = -2 \sum_{i<j} S_i \epsilon_{ij} S_j \epsilon_{ij} - \mu_0 \sum_i m_i e_i \cdot H_{\text{ext}}
- \sum_{i \in \text{TM}} D_{i} \epsilon_{i}^z + \sum_{i \in \text{RE}} \theta_{i}^{l_i} A_{l_i}^{m_i} (r_{l_i}) \hat{O}_{l_i}^{m_i},
\]

where \( S_i \epsilon_{ij} S_j \) is the exchange coupling constant including the spin amplitude between the \( i \)-th and \( j \)-th sites, \( e_i \) is the normalized spin vector at the \( i \)-th site, \( m_i \) is the magnetic moment, \( \mu_0 \) is the magnetic permeability of a vacuum and \( H_{\text{ext}} \) is the external magnetic field. The third and fourth terms include single-ion magnetic anisotropy properties. We consider transition metals (TM) and rare-earth elements (RE) separately. The anisotropy of TM sites is defined using the magnetic anisotropy parameter \( D_{l} \) and the \( z \)-component of \( e_i \), i.e., \( \epsilon_{i}^z \). The anisotropy of RE sites is based on crystal field theory and uses the Stevens operator \( \hat{O}_{l_i}^{m_i} \), crystal field parameter \( A_{l_i}^{m_i} \), and Stevens factors \( \theta_{i}^{l_i} \). Here, \( \langle r_{l_i} \rangle \) can be calculated as the spatial average of the 4f electron distribution. In the present paper, we consider \( m_l = 0 \) for simplicity. For reference, note that \( \hat{O}_{l_i}^{m_i} = 0 \) and \( \theta_{i}^{l_i} = \frac{3}{2} \):

\[
\hat{O}_{l_i}^{0} = 3(J_i^z)^2 - J_i^z,
\hat{O}_{l_i}^{1} = 35(J_i^z)^4 - 30J_i^z - 25(J_i^z)^2 + 3J_i^z - 6J_i^2,
\hat{O}_{l_i}^{2} = 231(J_i^z)^6 - 315J_i^2 - 735(J_i^z)^4
+ [105J_i^2 - 525J_i^2 + 294](J_i^z)^2
- 5J_i^6 - 40J_i^4 + 60J_i^2,  
\]

\[
\theta_{i}^{l_i} = \begin{cases} 7 & \text{for } l_i = 2, \\ -2 & \text{for } l_i = 4, \\ -5 & \text{for } l_i = 6, \end{cases}
\]

Table I lists the atomic-scale parameters used in the present study. The 68 atoms in the tetragonal unit cell of Nd\(_{2}\)Fe\(_{14}\)B (see Fig. 1) occupy nine crystallographically inequivalent sites, as seen in Table I. These atom locations and lattice constants \( \mathcal{A} - \mathcal{C} \) were set to experimental values, especially below room temperature, \( T_R \sim 300 \text{ K} \).

TABLE 1. Site occupancies and model parameters of each crystallographically inequivalent atom. The spin magnetic moments, \( m_s \), are calculated from the first-principles calculation code, Machikaneyama (AkaiKKR). The anisotropy parameters \( D_{l}^{\lambda} \) and \( A_{l}^{m_i} (r_{l_i}) \) are taken from previous results. We neglected the \( D_{l}^{\lambda} \) values of B and Nd, as they are less than 0.1 meV, and used the \( \langle r_i \rangle \) values of Nd, Ref. 33, i.e., \( \langle r^2 \rangle = 1.00 \ a_B^2 \), \( \langle r^4 \rangle = 2.401 a_B^4 \), and \( \langle r^6 \rangle = 12.396 a_B^6 \), where \( a_B \) is the Bohr radius.

| atom | occ. | \( m_s \) | \( \mu_B \) | \( D_{l}^{\lambda} \) [meV] | \( A_{l}^{m_i} (r_{l_i}) \) [K] |
|------|------|----------|---------|-----------------|-----------------|
| Fe(g) | 4 | -0.169 | - | - | - |
| Fe(c) | 4 | 2.531 | -2.14 | - | - |
| Fe(e) | 4 | 1.874 | -0.03 | - | - |
| Fe(j1) | 8 | 2.298 | 1.07 | - | - |
| Fe(j2) | 8 | 2.629 | 0.58 | - | - |
| Fe(k1) | 16 | 2.063 | 0.55 | - | - |
| Fe(k2) | 16 | 2.206 | 0.38 | - | - |
| (l, m_l): | (2, 0) | (4, 0) | (6, 0) | - | - |
| Nd(j) | 4 | -0.413 | - | 295.3 -29.5 -22.8 |
| Nd(g) | 4 | -0.402 | - | - | - |
The higher-order crystal field parameters \( A_i^q \) and \( A_i^p \) of the Nd atoms have a significant effect on the low-temperature properties of \( \text{Nd}_2\text{Fe}_{14}\text{B} \). To illustrate these effects, Fig. 2 shows the anisotropy potential for \( J = 9/2 \) single classical spin:

\[
V_l^{mi}(θ) = \hat{Θ}_i^{2} A_l^m(r^l) O_l^m(θ),
\]

where \( θ \) is the spin angle measured from the \( z \)-axis (i.e., \( e^z = \cos θ \)) and \( A_l^m(r^l) \) take the values in Table II. The potential \( V_2 \) increases monotonically as \( θ \) increases, whereas \( V_4 \) and \( V_6 \) vary non-monotonically. Because of this behavior, the total anisotropy potential \( V_2^0 + V_4^0 + V_6^0 \) attains a minimum at \( θ = 36.7^o \) for (a) \( J_z = e^z J \). In contrast, for (b) \( J_z = 0.8e^z J \), the minimum occurs at \( θ = 0^o \). This coefficient (= 0.8) of \( e^z \) can be regarded as an effect of thermal fluctuations at \( T > 0 \). The above results indicate that the spin direction is tilted from the \( z \)-axis at \( T = 0 \), although this tilting disappears at a certain temperature. This behavior corresponds to the spin re-orientation phenomenon. In the case of \( \text{Nd}_2\text{Fe}_{14}\text{B} \), the spin reorientation transition is due to the \( V_4 \) and \( V_6 \) values of Nd atoms, and includes the effects of exchange couplings and the magnetic anisotropy of Fe atoms (for details, see Sec. IIIA).

Figure 3 shows the exchange coupling constants, \( S_i J_{ij} S_j \), which include the spin amplitude as a function of interatomic distance \( r_{ij} \). These constants were calculated with Liechtenstein’s formula\( ^{23} \) that has been implemented on the first-principles electronic-structure calculation using the Korringa-Kohn-Rostoker (KKR) Green’s function method, Machikaneyama (AkaiKKR)\( ^{24} \). In the calculation, standard muffin-tin-type potentials were assumed, and the local density approximation parametrized by Morruzzi, Janak and Williams\( ^{25} \) was used. Up to \( d \)-wave scatterings were taken into account in KKR, and \( (8 \times 8 \times 6) \) \( k \)-points in the first Brillouin zone being used for the calculation of \( J_{ij}^{\text{ex}} \)‘s. For the Nd \( 4f \)-states, the so-called open-core approximation was employed.

From Fig. 3 we can see that the exchange couplings between Fe and Nd have much smaller values than those between Fe atoms. In addition, none of the Nd atoms interacts directly with other Nd atoms. The amplitude relation of the exchange couplings is consistent with experimental results\( ^{29} \) based on a mean field analysis. Note that all \( S_{\text{Fe}} J_{\text{Fe-Nd}}^{\text{ex}} S_{\text{Nd}} \) on \( r_{ij} < 4 \AA \) have positive values in Fig. 3 As \( J_{ij}^{\text{ex}} \) is evaluated as the interaction between valence electrons, \( S_{\text{Fe}}(\text{Nd}) \) can be regarded as being proportional to \( m_{\text{Fe}}(\text{Nd}) \), i.e., \( S_{\text{Nd}} S_{\text{Fe}} < 0 \). Hence, the bare exchange couplings \( J_{\text{Fe-Nd}}^{\text{ex}} \) have negative values. The couplings between Fe and B, \( J_{\text{Fe-B}}^{\text{ex}} \), also take negative values which can be explained in the same way.

### B. Method

To analyze the finite-temperature magnetism of \( \text{Nd}_2\text{Fe}_{14}\text{B} \), we applied MC methods based on the Metropolis algorithm\( ^{30} \) to the above classical Heisenberg model. Although the magnetic anisotropy is evaluated as the magnetization angle dependence of free energy, this is generally difficult to simulate explicitly using a typical MC approach. Therefore, we also adopted the CMC method\( ^{31} \) to evaluate the magnetic anisotropy. The CMC method fixes the direction of total magnetization \( \mathbf{M} = (M_x, M_y, M_z) = (1/N_s) \sum_i m_i \mathbf{e}_i \) \( (N_s \) is the total number of sites) in any direction for each MC sampling without \( \mathbf{H}_{\text{ext}} \), and then calculates the fixed angle \( θ \) dependencies of free energy \( \Delta F(θ) \) and magnetization torque \( \mathbf{T}(θ) \) as follows:\( ^{19} \)

\[
\mathbf{T}(θ) = -\left\langle \sum_i \mathbf{e}_i \times \frac{∂\mathbf{H}}{∂\mathbf{e}_i} \right\rangle \quad \text{for} \quad \mathbf{M} = \mathbf{M}(θ),
\]

\[
\Delta F(θ) = F(θ) - F(θ_0) = \int_{θ_0}^{θ} dθ' \left[ \mathbf{n}(θ') × \mathbf{T}(θ') \right] \left. \frac{∂\mathbf{n}(θ)}{∂θ} \right|_{θ=θ'} ,
\]

where \( \mathbf{n}(θ) = \mathbf{M}(θ)/|\mathbf{M}(θ)| \) and \( \mathbf{M}(θ) \) is the total magnetization in the fixed direction \( θ \).
Note that Asselin et al.\textsuperscript{15} formulated the C-MC method for systems with homogeneous magnetic moments, i.e., all the magnetic moments have same value. However, it can easily be extended to systems with inhomogeneous magnetic moments such as Nd\textsubscript{2}Fe\textsubscript{14}B. We now briefly explain only the procedure of the extended C-MC method with a fixed $M$ in the direction of $z$-axis:

(A) Select a site $i$ and obtain the new state of $i$-spin randomly chosen,

$$e_i \rightarrow e'_i.$$  

(B) Select a site $j(\neq i)$ randomly.

(C) Adjust the new state of the $j$-spin to preserve $M$ direction (namely, $M_z = M = 0$):

$$
e_j \rightarrow e'_j,$$

$$e^{z'}_j = e^{z'}_j + \frac{m_i}{m_j}(e_z^i - e_z^{z'}),$$

$$e^{y'}_j = e^{y'}_j + \frac{m_i}{m_j}(e_y^i - e_y^{y'}),$$

$$e^{x'}_j = \text{sign}(e_z^j)\sqrt{1 - (e_z^{z'})^2 - (e_y^{y'})^2}.$$  

If $1 - (e_z^{z'})^2 - (e_y^{y'})^2 < 0$, return to (A).

(D) Calculate the new total magnetization:

$$M' = M + \frac{1}{N_a} \left[ m_i(e'_i - e_i) + m_j(e'_j - e_j) \right].$$  

If $M' < 0$, return to (A).

(E) Update from the initial spin states $(e_i, e_j)$ to the new spin states $(e'_i, e'_j)$ with the probability:

$$P = \min \left( 1, \frac{M'_z}{M_z} \right)^2 \frac{\left| e^z_j \right|}{\left| e^{z'}_j \right|} \exp(-\beta\Delta E),$$

where $\beta$ is the inverse temperature and $\Delta E = E(e'_i, e'_j) - E(e_i, e_j)$ is the energy difference.

(F) Return to (A).

To apply C-MC method to the Nd\textsubscript{2}Fe\textsubscript{14}B bulk system, we change the procedures (C) and (D) to treat different magnetic moments from those in the original paper\textsuperscript{15}

The MC (C-MC) simulations in the present study repeated each calculation for 200,000 (100,000) MC steps, where one MC step is defined as one trial for each spin to be updated. The first 100,000 (30,000) MC steps were used for equilibration, and the following 100,000 (70,000) MC steps were used to measure the physical quantities. We performed simulations for 12 different runs with different initial conditions and random sequences. We then calculated the average results and statistical errors. To check the system-size dependence, we used systems of $N_a = L^3 \times 68$ (unit cell) sites with $L = 3 - 6$, imposing the periodic boundary conditions.

Note that Asselin et al.\textsuperscript{15} formulated the C-MC method for systems with homogeneous magnetic moments, i.e., all the magnetic moments have same value. However, it can easily be extended to systems with inhomogeneous magnetic moments such as Nd\textsubscript{2}Fe\textsubscript{14}B. We now briefly explain only the procedure of the extended C-MC method with a fixed $M$ in the direction of $z$-axis:

(A) Select a site $i$ and obtain the new state of $i$-spin randomly chosen,

$$e_i \rightarrow e'_i.$$  

(B) Select a site $j(\neq i)$ randomly.

(C) Adjust the new state of the $j$-spin to preserve $M$ direction (namely, $M_z = M = 0$):

$$e_j \rightarrow e'_j,$$

$$e^{x'}_j = e^{x'}_j + \frac{m_i}{m_j}(e^x_i - e^x_{x'}),$$

$$e^{y'}_j = e^{y'}_j + \frac{m_i}{m_j}(e^y_i - e^y_{y'}),$$

$$e^{z'}_j = \text{sign}(e_z^j)\sqrt{1 - (e_x^{x'})^2 - (e_y^{y'})^2}.$$  

If $1 - (e_x^{x'})^2 - (e_y^{y'})^2 < 0$, return to (A).

(D) Calculate the new total magnetization:

$$M' = M + \frac{1}{N_a} \left[ m_i(e'_i - e_i) + m_j(e'_j - e_j) \right].$$  

If $M' < 0$, return to (A).

(E) Update from the initial spin states $(e_i, e_j)$ to the new spin states $(e'_i, e'_j)$ with the probability:

$$P = \min \left( 1, \frac{M'_z}{M_z} \right)^2 \frac{\left| e^z_j \right|}{\left| e^{z'}_j \right|} \exp(-\beta\Delta E),$$

where $\beta$ is the inverse temperature and $\Delta E = E(e'_i, e'_j) - E(e_i, e_j)$ is the energy difference.

(F) Return to (A).

To apply C-MC method to the Nd\textsubscript{2}Fe\textsubscript{14}B bulk system, we change the procedures (C) and (D) to treat different magnetic moments from those in the original paper\textsuperscript{15}

The MC (C-MC) simulations in the present study repeated each calculation for 200,000 (100,000) MC steps, where one MC step is defined as one trial for each spin to be updated. The first 100,000 (30,000) MC steps were used for equilibration, and the following 100,000 (70,000) MC steps were used to measure the physical quantities. We performed simulations for 12 different runs with different initial conditions and random sequences. We then calculated the average results and statistical errors. To check the system-size dependence, we used systems of $N_a = L^3 \times 68$ (unit cell) sites with $L = 3 - 6$, imposing the periodic boundary conditions.

For the model and parameter values, the results in this subsection are based on typical MC, rather than C-MC. Figure\textsuperscript{2} shows the magnetization curves for each effective exchange coupling radius $r_{\text{cut}}$. We consider all exchange couplings under $r_{ij} \leq r_{\text{cut}}$. Here, (A) is defined as the statistical average of $A$. It can be seen that there are two transition points in Fig.\textsuperscript{2}

In the higher-temperature region, $\langle |M_z| \rangle$ approaches 0 at the Curie temperature $T_c$. The magnetization curves show that $T_c$ is strongly dependent on $r_{\text{cut}}$, even in long-range ($r_{ij} > 3.52 \text{Å}$). Thus, $T_c$ was evaluated more accurately using the Binder parameter\textsuperscript{16} defined as $g_L = 1 - \langle |M| \rangle^4 / 3\langle |M|^2 \rangle^2$, for system sizes $L = 3 - 6$. The results are plotted in Fig.\textsuperscript{3}(a). It is apparent that $T_c$ has quite different values depending on $r_{\text{cut}}$, and the condition of $(8 \times 8 \times 6)$ $k$-points (mean accuracy of $S_i J_{ij}^0 S_j$).
in the first-principles calculations) is sufficient for convergence. Similar behavior can be seen in Fig. 3(b), where $T_C$ has been calculated by a 9-sublattice (i.e., 9 inequivalent sites in Table I) mean field analysis.\cite{39,40} Compared with the MC results, the mean field results are less sensitive to $r_{\text{cut}}$ and tend to overestimate $T_C$.

To analyze the long-range ($r_{ij} > 3.52 \, \text{Å}$) exchange coupling effect for $T_C$, Fig. 6 shows the average exchange coupling at the Fe atoms, $\tilde{J}_{\text{Fe}}(r_1, r_2)$, which is defined as follows:

$$\tilde{J}_{\text{Fe}}(r_1, r_2) = \frac{1}{N_{\text{Fe}}} \sum_{i \in \text{Fe}, j} S_i J_{ij}^{\text{ex}} S_j$$

where $N_{\text{Fe}}$ is the total number of Fe sites. Each bar height in Fig. 6 denotes the sum of $S_i J_{ij}^{\text{ex}} S_j$ per atom in the range of each bar width (here $r_2 - r_1 = 0.2 \, \text{Å}$). Because $\tilde{J}_{\text{Fe}}$ has many exchange bonds that correspond to a spherical surface area ($\propto r_{ij}^2$), it keeps small but significant value even in the long range. Indeed, the sum of short-range exchange couplings is $\tilde{J}_{\text{Fe}}(0, 3.52 \, \text{Å}) = 154.6 \, \text{meV}$ and that over a longer range is $\tilde{J}_{\text{Fe}}(3.52 \, \text{Å}, 17.6 \, \text{Å}) = -10.2 \, \text{meV}$. This negative value explains the decreasing trend for $T_C$ shown in Fig. 4. The necessity of long-range exchange coupling has been identified for bcc-Fe\textsuperscript{37,38} and MnBi\textsuperscript{39} and so the dependence of $r_{\text{cut}}$ appears to reflect the features of itinerant ferromagnetism. Under the condition that $r_{\text{cut}} = 3.52, 10.6, \text{and } 17.6 \, \text{Å}$, each atom has approximately 13, 350, and 1600 exchange coupling bonds, respectively. To reduce the computational load, we mainly consider $r_{\text{cut}} = 10.6 \, \text{Å}$.

At the lower temperature point $T_{sr}$ ($\sim 145 \, \text{K}$) in Fig. 4, $\langle |M| \rangle$ reaches a maximum and $M_{xy} = \sqrt{\langle M_x^2 \rangle + \langle M_y^2 \rangle}$ approaches 0, which is known to be the spin-reorientation transition of the Nd$_2$Fe$_{14}$B magnet. The magnetization direction is tilted 34.4º from the $z$-axis at $T = 0$ for every $r_{\text{cut}}$. Above $T_{sr}$, this direction exhibits uniaxial anisotropy along the $z$-axis. In contrast to $T_C, T_{sr}$ has only a weak dependence on $r_{\text{cut}}$. The spin-reorientation transition is mainly driven by the higher-order terms ($l = 4, 6$) of $A_l^{m=0}$ on the Nd atoms in Eq. 1. Indeed, in comparison to the tilting angle of the single Nd atom at $T = 0$ ($\theta = 36.7º$ in Fig. 4(a)), we can see that the Fe magnetic anisotropy has little effect on the spin reorientation. The reorientation property of Nd atoms is shared with the whole Nd$_2$Fe$_{14}$B through the exchange coupling $J_{\text{Fe-Nd}}^{\text{ex}}$. As shown in Fig. 4, most contributions of $J_{\text{Fe-Nd}}^{\text{ex}}$ are in the range $r_{\text{cut}} \leq 3.4 \, \text{Å}$. Therefore, $T_{sr}$ has only a weak dependence on the long-range parts of $J_{ij}^{\text{ex}}$.

To look into the role for each atom in the above two transition at $T_C$ and $T_{sr}$, we plot in Fig. 7 the temperature dependence of the magnetizations and the magnetization angle of Nd and Fe atoms. In Fig. 7(a), reduction of the magnetization amplitude $\langle |M| \rangle$ with the temperature of each atom shows clear difference. This difference is reflected by the amplitude of exchange couplings, $\tilde{J}_{\text{Fe}}^{\text{ex}} (\tilde{J}_{\text{Nd}}^{\text{ex}})$ for $r_1 = 0, r_2 = 10.6 \, \text{Å} = 142.9 \, \text{meV} (33.5 \, \text{meV})$. Hence, the ferromagnetic order of Fe is responsible to the magnetic order of the magnets. At high temperature, we may have a picture that the magnetization of Nd atom is maintained by the interaction with the ordered Fe. The rapidly decreasing of Nd magnetization with temperature corresponds to the poor thermal properties of magnetic anisotropy (see next section). On the other hand, from each magnetization angle $\theta$ in Fig. 7(c), we can verify that $T_{sr}$ is mainly depend on the magnetic anisotropy of Nd atoms as was mentioned in the previous paragraph. The magnetization angle $\theta$ is calculated by
FIG. 8. Angular dependence of $y$-direction torque $T_y$ (left side) and free energy $\Delta F$ (right side) at each temperature for $r_{\text{cut}} = 10.6$ Å and $L = 4$. The gray lines on the left side show the fit of the torque data to $-\partial \Delta F / \partial \theta$ in Eq. (8).

using $\langle |M_z| \rangle$ and $M_{xy}$ in Fig. 8(b) as follows:

$$\theta = \arctan \left( \frac{\langle |M_z| \rangle}{M_{xy}} \right). \quad (7)$$

In Fig. 8(c), the angle of Nd magnetization has always larger value than the angle of Fe magnetization below $T_{sr}$. This behavior implies that the spin-reorienation occurs because that the tilted Nd magnetization attracts the Fe magnetization.

It is necessary to keep in mind that the model parameters do not include the thermal variations of the lattice parameters and the electronic states. However, despite using many parameters from first-principles calculations, the above thermodynamic results ($T_C \sim 754$ K, $T_{sr} \sim 145$ K for $r_{\text{cut}} = 10.6$ Å) are basically consistent with experimental values ($T_C \sim 585$ K, $T_{sr} \sim 135$ K). Therefore, the model and the parameter sets are sufficiently reliable for studying the temperature dependence of magnetic anisotropy in Nd$_2$Fe$_{14}$B.

B. Temperature Dependence of Magnetic Anisotropy

We now discuss the temperature dependence of magnetic anisotropy. Figure 8 shows the $y$-direction torque $T_y$ and free energy $\Delta F$ as a function of magnetization angle $\theta$ for $L = 4$ as calculated by the C-MC method. In the present paper, the directions of magnetization constrained by the C-MC method are rotated by $\theta$ around the $y$-axis. Therefore, the torque is perpendicular to the $x$-$z$ plane, i.e., both the $x$ and $z$ components of torque are zero.

To verify the C-MC method, we compare the magnetic anisotropy energies $\mathcal{F}_A$ with those given by the typical MC method, $\mathcal{F}_A^H$. Here, $\mathcal{F}_A$ is defined as $\Delta F_{\text{max}} - \Delta F_{\text{min}}$ in Fig. 8 and $\mathcal{F}_A^H$ is derived from the magnetization curves as the gray area on the left of Fig. 9 (example at $T = 300$ K), where $\langle |M_x| \rangle$ is the magnetization curve under $H_{\text{ext}}$ in the $x$-$z$-direction. From the right of Fig. 9 we can confirm that $\mathcal{F}_A$ is in good agreement with $\mathcal{F}_A^H$, particularly in the low-temperature region, although $\mathcal{F}_A^H$ tends to give an overestimate. This overestimate occurs because, at finite temperatures, the effective magnetic anisotropy of each spin decreases as a result of thermal fluctuations. When evaluating $\mathcal{F}_A^H$, the thermal fluctuations are suppressed by the external field to saturate the magnetization. This suppression becomes stronger as the temperature increases, causing the overestimation to be significant in high-temperature region.

We also plot $\mathcal{F}_A$ for other calculation conditions: $(L, r_{\text{cut}}) = (4, 3.52)$ and $(5, 3.52)$ on the right of Fig. 9. These results show that a system size of $L = 4$ is sufficient to obtain convergence in the magnetic anisotropy. Additionally, the length of $r_{\text{cut}}$ affects $\mathcal{F}_A$ at high temperatures. As mentioned in terms of spin reorientation, the magnetic anisotropy of Nd is essentially unaffected by differences in $r_{\text{cut}}$. Hence, it can be regarded as that the difference between red and green lines in Fig. 9(b) occurs due to $r_{\text{cut}}$ dependence of Fe anisotropy. Therefore, in high-temperature region where Fe anisotropy becomes larger than the Nd anisotropy (see Fig. 11 $A_{\text{Fe}}^\text{ori} = 0$ and $D_A = 0$), the effects on $\mathcal{F}_A$ of differences in $r_{\text{cut}}$ are clearly evident.

Returning to Fig. 8 we can see that for 100 K and 125 K, the torque (free energy) curve attains a local maximum (minimum) at $\theta \neq 0$, which reflect the spin reorientation (shown in Fig. 8). In contrast, above $T \geq 200$ K, the local maximum (minimum) disappears and the torque (free energy) curve approaches $\propto \sin 2\theta \sin^2 \theta$. This behavior implies that the magnetic anisotropy con-
constant $K^A$ becomes dominant as the temperature increases. To clarify the temperature dependence, Fig. 11 shows the magnetic anisotropy constants $K^A_m$ ($m = 1, 2, 4$) that were calculated by fitting $T_N$ in Fig. 8 to the torque equation:

$$T_N(\theta, T) = \frac{\partial}{\partial \theta} \Delta F(\theta, T),$$

$$\Delta F(\theta, T) = K^A_1(T) \sin^2 \theta + K^A_2(T) \sin^4 \theta + K^A_4(T) \sin^6 \theta. \quad (8)$$

These constants can only be calculated correctly using the C-MC method. We can confirm that $K^A_2$ and $K^A_4$ tend to zero and $K^A_1$ becomes dominant in the region of $T > 300$ K. Additionally, $K^A_1$ becomes negative in the low-temperature region. This is reflected by the local minimum of $\Delta F$ in Fig. 8 indicating the spin re-orientation transition. The temperature dependence of $K^A_1$ agrees reasonably well with previous experimental results and mean field theory. Note that, at $T < 100$ K, all of the $|K^A_m|$ are significantly larger than the experimental values. For classical spin systems, this deviation in $K^A_m$ (and also $M$) is finite at zero temperature on account of the infinite degrees of freedom of classical spin (for quantum spin systems, the deviations of $K^A_m$ and $M$ at $T = 0$ are zero). This explain the difference between our results and the experimental results at $T < 100$ K.

To examine the relationship between the exchange coupling and magnetic anisotropy, we considered various input parameter sets. Figure 11 shows the anisotropy energy $F_A$ for five cases: the same result as shown by the red lines in Fig. 9 (default), a model including only Fe magnetic anisotropy ($A^m_{Fe} = 0$), a model including only Nd magnetic anisotropy ($A^m_{Nd} = 0$), a model with all $J^ex_{Fe-Nd}$ reduced by half ($0.5J^ex_{Fe-Nd}$) and a model with all $J^ex_{Fe-Nd}$ increased by half ($1.5J^ex_{Fe-Nd}$). In the case of $A^m_{Fe} = 0$, the anisotropy energy decreases almost linearly with temperature. This behavior is a typical property of the classical Heisenberg models that include only $\sin^2 \theta$ for the anisotropy energy. In contrast, the case of $D^A = 0$ exhibits a rapid decrease, which can be explained by the difference in the exchange coupling $J^ex_{atom}(r_1, r_2)$ of Nd and Fe atoms (see Eq. 5). We have that $J^ex_{Fe}$ and $J^ex_{Nd}$ for $r_1 = 0$, $r_2 = 10.6$ Å are $142.9$ meV and $33.5$ meV, respectively. Here, $J^ex_{Fe-Nd}$ is almost given by the Fe–Fe (Nd–Fe) exchange couplings (see Fig. 3). The Nd atoms, which give the whole Nd$_2$Fe$_{14}$B system magnetic anisotropy through $J^{ex}_{Nd}$, are highly susceptible to thermal fluctuations, unlike the Fe atoms, which play a key role in magnetism (such as $|M|$ and $T_C$). This difference in thermal susceptibility explains the rapid decrease in $F_A$ for $D^A = 0$. For the same reason, in the case of $0.5J^ex_{Fe-Nd}$, which includes both $A^m_{Nd}$ and $D^A$, $F_A$ decreases rapidly with temperature, and approaches $A^m_{Nd} = 0$ at approximately 400 K. This means that the effects of Nd magnetic anisotropy are almost wiped out by thermal fluctuations above 400 K. However, for $1.5J^ex_{Fe-Nd}$, $F_A$ is almost linear. The above discussion for Fig. 11 allows us to understand that $J^ex_{Nd}$ (rather than $J^ex_{Fe}$) makes a strong contribution to the magnetic anisotropy of Nd atoms, which supports the results of previous studies.

To analyze the results shown in Fig. 11 in the context of the Callen–Callen law, i.e., $K^A_1(T) \propto M(T)^3$ for $K^A_2 = K^A_4 = 0$, Fig. 12 illustrates the relationship between $K^A_1$ and $M$ above 300 K. It is clear that $1.5J^ex_{Fe-Nd}$ deviates from this law, because $K^A_2$ is comparable to $K^A_1$ at 300 K. Varying the anisotropy terms $A^m_{Nd}$ and $D^A$ affects these relations more than $J^ex_{Nd}$. For $A^m_{Nd} = 0$, Nd magnetization decreases rapidly with temperature, whereas Fe anisotropy decreases gradually. Hence, $K^A_1/M$ tends to increase. Conversely, for $D^A = 0$, Fe magnetization slowly decreases with temperature whereas Nd anisotropy decreases rapidly, hence $K^A_1/M$ tends to decrease. As above two effects happen to cancel out, the default case and $0.5J^ex_{Fe-Nd}$ agree with the Callen–Callen law.
FIG. 12. Relation between $K_1^A(T)$ and $M(T)$ at each temperature for the same parameter sets and calculation conditions in Fig. 11. The natural logarithm is taken for both axes. The Callen–Callen law corresponds to $M(T)$, illustrated by a dashed line.

The Callen–Callen law was derived under the assumption of homogeneous ferromagnetic and single-ion anisotropy systems at temperatures far from $T_C$. Therefore, it is natural that multi-sublattice model such as Nd$_2$Fe$_4$B does not follow the Callen–Callen law, which was also pointed out by using a mean field approach. Additionally, in actual ferromagnetic metals that have two-ion magnetic anisotropy, the temperature dependence of magnetic anisotropy deviates from the Callen–Callen law, as also pointed out by using a mean field approach.

C. Energy Barrier

Finally, we discuss the external magnetic field $H_{ext}$ response of the energy barrier (activation energy) which governs the probability of magnetization reversal via the thermal fluctuation of spins. If this response can be measured experimentally, it would allow the magnetic coercivity mechanism to be predicted at finite temperature dependence is needed to formulate the theory for itinerant electrons and inhomogeneous systems.

![Graph showing the relationship between $K_1^A(T)$ and $M(T)$](image)

**FIG. 13.** Height of the energy barrier, $F_B$, as a function of external magnetic field, $H_{ext}$, at each temperature for $r_{ext} = 10.6$ Å and $L = 4$. The gray lines illustrate the fit to Eq. (9).

**TABLE II.** Fitting parameters ($F_B^0$, $H_0$, $n$) at each temperature. The exponent $n_K$ was estimated with the single-spin model (Eq. (10)) using the anisotropy constant $K^A_m$ in Fig. 10 instead of $K_m$.  

| Temp. [K] | $F_B^0$ [MJ/m$^3$] | $H_0$ [T] | $n$ | $K^A_m$ | $K^A$ | $n_K$ |
|------------|-----------------|----------|-----|----------|----------|-------|
| 150        | 6.53            | 7.54     | 1.35| 9.35     | -2.55    | 1.56  |
| 200        | 5.37            | 6.23     | 1.42| 1.08     | -0.25    | 1.44  |
| 300        | 3.61            | 5.41     | 1.72| 0.2      | -0.04    | 1.72  |
| 400        | 2.46            | 4.44     | 1.90| 0.05     | -0.01    | 1.91  |
| 500        | 1.65            | 3.46     | 1.97| 0        | 0        | 2.00  |
| 600        | 1.03            | 2.55     | 2.00| -0.02    | 0        | 2.05  |

overcome the energy barrier, and so $H_c$ is much lower than $H_B$. The exponent $n$ can take various values, such as $n = 2$ for the Stoner–Wohlfarth model and $n = 1$ for the weak domain-wall pinning mechanism.

The parameters $F_B^0$, $H_0$, and $n$ were obtained by fitting $F_B(H_{ext})$ in Fig. 13 and are listed in Table II. We can see that $n$ takes values of less than 2 in the low-temperature region (below the room temperature, $T_R \sim 300$ K) and approaches 2 as the temperature increases. This reflects the fact that the magnetic anisotropy is mainly governed by the $K^A_1$ term in the high-temperature region (see Fig. 10). To clarify this, we estimated the exponent $n^*$ by fitting from the anisotropy energy of the single-spin model, which is defined as:

$$E_A^s(\theta) = \kappa_1 \sin^2 \theta + \kappa_2 \sin^4 \theta + \kappa_4 \sin^6 \theta + m H_{ext} \cos \theta.$$  (10)

With $\kappa_2 = \kappa_4 = 0$, this corresponds to the Stoner–Wohlfarth model. The dependence of the anisotropy constant on $n^*$ is plotted in Fig. 14. This figure confirms that $\kappa_2$ and $\kappa_4$ have a significant effect on $n^*$ for (a) $\kappa_1 > 0$, whereas $n^*$ is less sensitive for (b) $\kappa_1 < 0$, which corresponds to the low-temperature region below $T_m$ of Nd$_2$Fe$_4$B (see Fig. 10). Here, the deviation of $n^*$ given
This indicates that, in terms of the magnetic field and thermal fluctuations. For the Nd\(_2\)Fe\(_{14}\)B system, in particular, we should bear in mind that the response occurs for \(n < 2\) when below room temperature, \(T_R\), indicating Stoner–Wohlfarth-type magnetization rotation. This behavior reflects the fact that the magnetic anisotropy is mainly governed by the \(K^A\) term in \(T > T_R\), which is explained by the single-spin model with a renormalized \(K^A\).

Additionally, we input \(K^A\) (from Fig. 10) into \(\kappa_m\) in Eq. 10, and estimated the exponent \(n^s\) listed in Table II. Despite using the single-spin model, \(n^s\) is in good agreement with \(n\), where \(n\) has been evaluated on an inhomogeneous spin system such as Nd\(_2\)Fe\(_{14}\)B. This indicates that, in terms of the magnetic field response of uniform rotation, the anisotropy constants \(K^A\) are renormalized by the magnetic inhomogeneities and thermal fluctuations. For the Nd\(_2\)Fe\(_{14}\)B system, in particular, we should bear in mind that the response occurs for \(n < 2\) when below room temperature, \(T_R\).

**IV. SUMMARY**

We have constructed a realistic classical three-dimensional Heisenberg model using parameters from first-principles calculations, and investigated the magnetic properties of the Nd\(_2\)Fe\(_{14}\)B bulk system at finite temperatures. Applying the constrained Monte Carlo method to this model, from atomic-scale parameters, we evaluated macroscopic magnetic anisotropies which include correctly magnetic inhomogeneities and thermal fluctuations. Despite using many parameters from first-principles calculations (except for \(A_i^{(n)}\)), the model reproduced the experimentally observed spin reorientation and magnetic anisotropy constants \(K^A\).

Using this calculation system, we found that, because the exchange couplings between Nd moments and Fe spins are much smaller than those between Fe spins, the magnetic anisotropy of Nd atoms decreases more rapidly than that of Fe atoms. Additionally, owing to this magnetic inhomogeneity, the temperature dependence of \(K^A\) deviates from the Callen–Callen law, even above room temperature \((T_R \sim 300\,\text{K})\), when the Fe (Nd) anisotropy terms are removed to leave only the Nd (Fe) anisotropy. Furthermore, we also found that the exponent \(n\) in the magnetic field response of barrier height is less than 2 in the low-temperature region below \(T_R\), whereas \(n\) approaches 2 when \(T > T_R\), indicating Stoner–Wohlfarth-type magnetization rotation. This behavior reflects the fact that the magnetic anisotropy is mainly governed by the \(K^A\) term in \(T > T_R\), which is explained by the single-spin model with a renormalized \(K^A\).

We have a plan to extend the constructed framework in present paper to non-uniform magnetization reversal in finite-size particles, including the effects of the grain surfaces or grain boundaries.

**ACKNOWLEDGMENTS**

We would like to thank D. Miura, R. Sasaki, M. Nishino, Y. Miura, and S. Hirosawa for useful discussions and information. This work is supported by the Elements Strategy Initiative Project under the auspices of MEXT.
