Nebulin is about 800 kDa filamentous protein that binds the entire thin filament of vertebrate skeletal muscle sarcomeres. Nebulin cannot be isolated from muscle except in a completely denatured form by direct solubilization of myofibrils with SDS because nebulin is hardly soluble under salt conditions. In the present study, nebulin was solubilized by a salt solution containing 1 M urea and purified by DEAE-Toyopearl column chromatography via 4 M urea elution. Rotary-shadowed images of nebulin showed entangled knit-like particles, about 20 nm in diameter. The purified nebulin bound to actin filaments to form loose bundles. Nebulin was confirmed to bind actin, α-actinin, β-actinin, and tropomodulin, but not troponin or tropomyosin. The data shows that full-length nebulin can be also obtained in a functional and presumably native form, verified by data from experiments using recombinant subfragments.

1. Introduction

Single molecules of nebulin (the precise molecular weight expressed in a certain tissue depends on the respective splice isoform; for a 773 kDa species, see [1]) associate along the entire length of the thin filament of vertebrate skeletal muscle. Therefore, nebulin is thought to be a molecular ruler for determining length of \( \sim 1 \) \( \mu \)m [2–4]. To ascertain such potential of nebulin, its effect on the length of actin filaments should be examined in vitro. However, nebulin has not been successfully isolated from skeletal muscle due to difficulties in solubilization under salt conditions, although isolation of a completely denatured nebulin has been achieved by gel filtration of SDS-solubilized myofibrils [5].

Complete sequencing of human nebulin by Labeit and Kolmberger showed that a large portion (97%) of nebulin comprises 185 repeats of approximately 35 amino acids with a central consensus sequence of SDXXYK [1].

In the sarcomere, the N-terminal region of nebulin localizes at the pointed end of the thin filaments, central region along the thin filaments, and C-terminal region in the Z-line [2]. Each nebulin repeat (SDXXYK) can bind to actin [6–8], while nebulin repeats 1–3 bind to tropomodulin [9], 163–170 bind to desmin [10], 185–SH3 domain bind to connectin (also called titin) [11], and the SH3 domain binds to myopalladin [12] and β-actinin (also called CapZ) [11].

In 2009, Yadavalli et al. reported that they extracted full-length nebulin from rabbit longissimus dorsi muscle using 0.45% sodium deoxycholate (DOC), and then purified it with an NaCl gradient in the presence of 0.45% DOC. However, the detailed preparation method has not been published yet [13].

In the present study, we describe the purification of nebulin from rabbit skeletal muscle. For solubilization, 1 M urea was required, and during purification, 4 M urea were employed. Using these conditions, a purification procedure for nebulin was developed. The purified nebulin was confirmed to bind actin filaments and to form loose bundles, and therefore was able to adopt a folded state.

2. Materials and Methods

2.1. Protein Preparations. Actin was prepared from an acetone powder of rabbit skeletal muscle by the method of
Spudich and Watt [14] and further purified by gel filtration through a Sephadex G-150 column equilibrated with 0.2 mM ATP, 0.1 mM CaCl2, 0.01% NaN3, and 2 mM Tris/HCl, pH 8.0. β-Actinin was purified from rabbit skeletal muscle as reported by Maruyama et al. [15], and α-actinin was prepared from rabbit skeletal muscle by the method of Goll et al. [16]. Tropomodulin was isolated from rabbit skeletal muscle as described previously [17]. Tropomyosin was extracted from actin-extracted acetone powder of rabbit skeletal muscle and purified according to Woods [18], and troponin was prepared from rabbit skeletal muscle by the method of Goll et al. [16]. Tropomodulin was isolated from rabbit skeletal muscle and purified according to Woods [18], and troponin was prepared from rabbit skeletal muscle using the method described by Ebashi et al. [19]. The purity of the binding partners (actin, tropomyosin, troponin, tropomodulin, and β-actinin) was described in Figure 1 of the tropomodulin paper in 1999 [17], and the purity of α-actinin was described at lane 2 in Figure 6 of the amphioxus nebulin paper in 2009 [20].

2.2. SDS-Polyacrylamide Gel Electrophoresis (PAGE) and Immunoblotting. Isolated protein samples were resolved by SDS-PAGE using 2–15% gradient polyacrylamide gels, and then transferred to nitrocellulose membranes. Membranes were treated with primary antibodies followed by secondary horseradish-labeled antibodies (Dako). Polyclonal antibodies to nebulin (PcNeb) [21], actin (A2066, Sigma-Aldrich), and connectin (Pc1200) [22] and the monoclonal antibody to connectin (Mc3B9) [23] were used.

2.3. Electron Microscopy. Negative staining was examined using 2% uranylacetate with the JEOL JEM-100S electron microscope.

2.3.1. Rotary-Shadowed Electron Microscopy. A purified nebulin solution in 50% glycerol was dropped onto a mica plate. In the case of centrifuging, the mica-taped rotor was centrifuged for 25 s at 12,000 × g as previously reported [24–26]. The sample was rotary-shadowed at 7.5° with platinum-carbon, followed by carbon on the uncooled specimen stage of a JEOL JFD-9000 freeze fracture apparatus. The resulting specimen was observed under a JEOL 100S electron microscope.

2.4. Binding Tests by Cosedimentation. Nebulin from modified purification was dialyzed against 0.18 M KPO4 (pH 7.0), 0.1 mM MgCl2, 0.1 mM EGTA, and 0.5 M urea overnight and then centrifuged for 30 minutes at 56,000 × g. The supernatant of nebulin was mixed with G-actin in 0.11 M KPO4, 0.27 mM ATP, 0.1 mM MgCl2, and 0.31 M urea, pH 7.0 at 4°C for 20 hours. The mixture was centrifuged (6,000 × g, 4°C, 30 min), and the supernatant and pellet were diluted with SDS sample buffer and subjected to SDS-PAGE.

2.5. Binding Tests by Far Western Blotting. Proteins (0.2 μg) adsorbed onto a nitrocellulose membrane were first blocked with 0.2% gelatin in Tris-buffered saline and then incubated in nebulin solution (0.18 M KPO4 (pH 7.0), 0.1 mM MgCl2, 0.1 mM EGTA, and 0.5 M urea) (15 μg/ml) for 20 hours at 4°C. After washing, the membrane was treated with antinebulin polyclonal antibody [21] followed by secondary horseradish-labeled antibodies (Dako).

3. Results

3.1. Isolation of Nebulin from Rabbit Skeletal Muscle. Preliminary trials to solubilize nebulin from rabbit skeletal myofibrils proved unsuccessful under conventional salt conditions. However, with the addition of 1 M urea, a solution containing 0.18 M KPO4 (pH 7.0) and 0.1 mM EGTA could solubilize nebulin together with myosin, actin, and other muscle proteins. Purification by DEAE-Toyopearl column chromatography yielded a fraction containing nebulin and actin. However, it was very difficult to separate the two proteins. Thus, we modified the procedure to prevent actin from denaturation.

Rabbit skeletal muscle (approximately 120 g) was briefly homogenized in 1 L of 50 mM KCl solution containing 1 mM NaHCO3 and 1 mM EGTA and then sedimented by centrifugation for 6 minutes at 5,000 × g, and all procedures were carried out at 4°C. The precipitate was suspended in the same solution and recentrifuged. This procedure was repeated four times. After washing with 5 mM NaHCO3, the pellet was extracted with 1 L of 0.2 M NaPO4 (pH 7.0) to remove connectin and then with 0.3 M KCl-0.15 M KPO4 (pH 7.0) to remove myosin. The pellet was washed three times with cold 0.1 mM MgCl2, and the swollen precipitate
was extracted at 4°C for 15 minutes with an equal volume of
the same precipitate in a solution with a final concentration
of 0.18 M KPO₄ (pH 7.0), 0.2 mM ATP, 0.1 mM MgCl₂,
and 0.1 mM EGTA, plus 1 M urea, which was required for
nebulin extraction (Figure 1(A)-a). The sample was loaded
onto the DEAE-Toyopearl 650 M column (1.9×18 cm)
equilibrated with 0.18 M KPO₄ (pH 7.0), 0.1 M MgCl₂,
0.1 mM EGTA, and 1 M urea, where a large amount of
solubilized myosin and other proteins were not absorbed on
the DEAE-Toyopearl resin (Figure 1(A)-b). Bound proteins
were eluted by a gradient of 1 to 4 M urea. Actin and nebulin
were eluted at around 2 M (Figures 1(A)-c and 1(A)-e, urea, respectively. Further elution with
4 M urea overnight (0.02-0.03 mg/ml) was more e
fective
at eluting nebulin (Figure 1(A)-f); however, these fractions
contained traces of connectin (also called titin) (Figures
1(A)-e and 1(A)-f). The eluates were dialyzed against 0.18 M
KPO₄ (pH 7.0), 0.1 mM MgCl₂, 0.1 mM EGTA, and 2 M urea
and then centrifuged for 30 minutes at 12,000 × g. The
supernatant was loaded onto the hydroxylapatite column
equilibrated with the dialysis solution. As connectin was
adsorbed onto the column, nebulin alone was obtained as the
flow through fraction (Figure 1(A)-HyAp), but in low yield:
0.03–0.06 mg nebulin (from 120 g rabbit skeletal muscle).

Immunoblotting clearly showed specific reaction to
the purified nebulin fraction using anti-nebulin antibody
(Figure 2(b)-2); no reaction was observed for anti-actin
and anti-connectin antibodies (Figures 2(b)-3, 2(b)-4, and
2(b)-5).

3.2. Modified Purification Method for Nebulin. The protein
yield was too low because our procedure was a pared prepa-
ration of nebulin. Therefore, we modified the procedure
to improve the overall yield of nebulin. First, the well-
washed myofibrils were extracted with 0.18 M KPO₄ (pH
7.0), 0.1 mM MgCl₂, 0.1 mM EGTA, and 1 M urea without
the addition of ATP, which resulted in a smaller amount
of extracted myosin (Figure 3(A)-b) than for extraction in
the presence of ATP (Figure 1(A)-b). Consequently, nebulin
was extracted to a larger extent under the same DEAE-
Toyopearl column chromatography conditions described
above. Overnight reelution with 4 M urea thus resulted in
a nebulin solution of 1–1.5 mg/ml, although it was slightly
contaminated with actin (Figure 3-f)).

3.3. Electron Microscopy of Isolated Nebulin. Rotary shad-
owing was applied to purified nebulin samples for visual-
ization of its electron microscopic structure. The nebulin
fraction contaminated with traces of connectin (prior to
hydroxylapatite chromatography, Figures 1(A)-e and 1(A)-
f) showed a number of particles and few entangled filaments
(data not shown). Upon further purification of nebulin, the
entangled filaments disappeared leaving only small particles
(Figure 4), indicating that the filaments were contaminated
with connectin molecules, as has been reported previously
[25].

The remaining particles having approximately 20-nm in
diameter were regarded to be nebulin molecules (Figure 4).
The particles had an irregular shape and formed a compact
bundle of actin filaments, suggesting a densely aggregated
form of the long nebulin molecule. Further application of
centrifugal forces to extend these filamentous molecules as
3.4. Interaction of Actin with Purified Nebulin. Purified nebulin was clarified by ultracentrifugation (30 min, 56,000 × g) and then mixed with G-actin. To polymerize G-actin, the solution conditions were changed to 0.11 M KPO₄ (pH 7.0), 0.31 M urea, 0.27 mM ATP, and 0.1 mM MgCl₂. The concentration of G-actin and nebulin was 0.2 mg/ml and 19 μg/ml, respectively, giving a 1:188 molar ratio of nebulin to actin. After 20 hours incubation at 4°C, the samples were centrifuged for 30 minutes at 6,000 × g. As shown in Figure 5, nebulin coprecipitated with actin whereas nebulin alone did not precipitate; a small amount of actin alone was also precipitated. Thus, the large bundles of actin filaments were formed in the presence of nebulin, which was verified by negative-stained electron micrographs (Figure 6).

3.5. Binding of Thin Filament Proteins to Purified Nebulin. The interaction of nebulin with several actin-binding proteins was examined by far western blot analysis. As shown in Figure 7, α-actinin and F-actin strongly bound to nebulin. β-Actinin and tropomodulin weakly bound to nebulin, while troponin and tropomyosin showed no binding ability.

4. Discussion

Since nebulin is very insoluble in salt, until now it could only be extracted and purified in the presence of a detergent such as SDS [5]. In this study, however, we were able to extract nebulin from the skeletal muscle of a rabbit by adding 1 M urea to 0.18 M KPO₄ (pH 7.0). However, when we removed all of the urea from this nebulin crude extract solution by dialysis, the solubility of the nebulin deteriorated remarkably, and most of it precipitated. Therefore, in order to prevent nebulin from interacting with other proteins and decreasing its solubility, we purified it by column chromatography in the presence of urea.

We also tried eluting the nebulin from an ion-exchange column chromatography in a salt concentration gradient, but we were unable to remove the contaminants. We therefore, used a urea concentration gradient for elution. After the elution in the urea concentration gradient was complete, we let the nebulin stand for 12 hours and eluted it again. Consequently, we obtained a high-concentration fraction of nebulin. The reason we were able to obtain this high-concentration fraction of nebulin after the second elution, not after the first elution, might be that the nebulin needed time to dissociate from the resin in the column chromatography since the urea with which the nebulin was eluted was at a concentration of 4 M, the minimum concentration necessary for the elution. In this study, we were unable to perform a circular dichroism spectra measurement of the purified nebulin because its content was too low. However, the results of electron microscopic observation and the fact that nebulin could bind to actin suggested that the purified nebulin corresponded at least to a significant extent to a folded state.

Since nebulin is known to exist along thin filaments in skeletal muscle sarcomeres, it is thought to have a filamentous molecular shape. However, observation of isolated nebulin by the rotary shadowing method revealed that its molecular shape was not filamentous but a lump with about 20 nm in diameter (Figure 4). Both in the nebulin fraction obtained in the low urea concentration and the nebulin solution whose urea concentration was reduced by dialysis, the shape of nebulin was same as the nebulin eluted in 4 M urea. Even when the nebulin was dialyzed in pH 9.0 solution because the pI of nebulin is 9.3 [1], we did not see any change in this shape. Furthermore, even though we tried elongating the nebulin molecules by centrifuging them just like connectin, we were unable to see any change in molecular
shape. We were also unable to elongate the lump-shaped molecules even when we used nonionic or amphoteric detergent. However, when we used the anionic detergent SDS, the lumped-shape molecules mostly disappeared, and we observed amorphous images (data not shown). These results suggest that since nebulin molecules are insoluble in salt, they become entangled after they are isolated from skeletal muscle. In contrast, the filamentous form of nebulin in skeletal muscle sarcomeres is probably maintained by their interaction with actin.

In this study, a cosedimentation assay revealed that nebulin isolated from skeletal muscle bound to actin (Figure 5). Other studies have verified by the ELISA method and by cosedimentation assays that the protein which is a part of the nebulin expressed in *Escherichia coli* bound to actin [6, 27–32], and the binding results of our study are consistent with the results of these studies.

Based on the contents of total proteins in muscle in vivo, it has been calculated that there are 2 molecules of nebulin per thin filament [2, 4]. Furthermore, since it has been estimated from the primary structure that 1 molecule of actin corresponds to 1 module of nebulin in a thin filament [1, 3, 4], human nebulin is calculated to interact with 185 actin molecules. We performed a cosedimentation assay of nebulin with actin at a ratio based on this calculation, but not all of the actin precipitated, and only part of it bound to nebulin (Figure 5). This may have been because only part of the actin-binding site of nebulin acts on actin.

On the other hand, the assay also showed that actin filaments were bundled by nebulin (Figure 6(c)). In 1998, Gonsior et al. reported that actin filament bundles were formed by the mixing of F-actin and proteins of 6 nebulin modules expressed in *E. coli* [31]. In our study, the bundles of actin filaments formed by the purified nebulin were
The N-terminal region of nebulin is known to bind to TMD which is a pointed end actin-capping protein [9], and the C-terminal region of nebulin is known to bind to β-actinin, which is a barbed end actin-capping protein. Our study showed that purified nebulin also bound to both TMD and β-actinin even though the reaction was weak (Figure 7). The reason that this binding is weak may be that the binding region of the nebulin molecule is at its terminus and is only a small portion of the entire molecule. Our study and others have shown that nebulin binds to actin capping proteins on both ends of the actin filaments. This result supports the idea that nebulin regulates the length of actin filaments.

Because nebulin is extremely insoluble in salt, biochemical analysis has not yet made progress. The novel purification method described here is likely to support future functional studies on nebulin since it provides a full-length source of nebulin peptide that allows to further study its role in thin filament assembly and its potential ruler functions.

5. Conclusion

In this study, nebulin was solubilized by 0.18 M KPO₄ (pH 7.0) solution containing 1 M urea and purified by DEAE-Toyopearl column chromatography via 4 M urea elution. The nebulin molecule took on a lump-like molecular shape, and we were unable to observe any molecular-ruler function. However, since the nebulin purified by the present method bound to actin and actin-capping proteins (β-actinin and tropomodulin), this nebulin may have retained some of its in vivo functions. In the future, it may become important to perform more detailed investigations of nebulin's biochemical characteristics, such as whether isolated nebulin retains its high-order structure. It may also become important to keep the concentration of urea low when purifying nebulin.
