(Dated:)

Using available quantum Monte Carlo predictions for a strictly 2D electron gas, we have estimated the spin susceptibility of electrons in actual devices taking into account the effect of the finite transverse thickness and finding a very good agreement with experiments. A weak disorder, as found in very clean devices and/or at densities not too low, just brings about a minor enhancement of the susceptibility.

PACS numbers: 71.45.Gm, 71.10.Ca, 71.10.-w, 73.21.-b

Spin fluctuations are believed to play an important role in the two dimensional electron gas (2DEG), near the apparent metal-insulator transition observed at low temperature in clean devices, with lowering the density. Indeed, it has been found that the application of an in-plane magnetic field, which polarizes the electron spin, suppresses the metallic conductivity and depending on the system occupies a finite transverse thickness, (ii) suffers scattering by a magnetic instability, has recently prompted a number of experimental investigations of the spin susceptibility \( \chi_s \) of the 2DEG, which is generally found to increase in an appreciable manner when decreasing the density. Similar behavior is found also on the theoretical side for a strictly 2DEG, according to the most recent (and most accurate) quantum Monte Carlo (QMC) results. However the susceptibilities measured in different devices differ among each other and, with one exception, do not agree with the theory. Evidently, details of the devices play a role in determining the properties of the 2DEG and should be accounted for by the theory, as we shall show below. In particular in experiments the electron gas (EG) (i) has a finite transverse thickness, (ii) suffers scattering by a number of sources (scattering which in fact determines its mobility), and depending on the system (iii) occupies one or two degenerate valleys. In this Letter we address points (i) and (ii) for one-valley systems, exploiting the available QMC data. We find that taking into account the finite thickness of the specific device quantitatively brings into agreement theory and experiment and reconciles measurements on different systems, whereas details of scattering sources play a minor role. Furthermore, we offer some comments on the effect of (iii) valley degeneracy.

At zero temperature and at given number density \( n \), the state of the 2DEG can be specified by the spin polarization \( \zeta = (n_\uparrow - n_\downarrow)/n \). The spin susceptibility \( \chi_s = (\partial \zeta/\partial B)_{B=0} \), which measures the ratio of the induced spin polarization to an in-plane applied weak magnetic field \( B \), is readily shown to be inversely proportional to the derivative \( (\partial^2 E(\zeta)/\partial \zeta^2)_\zeta=0 \), involving the EG internal energy \( E(\zeta) \). In fact minimization of the energy per particle \( E(\zeta) + \zeta g_B B/2 \) with respect to \( \zeta \) yields the condition \( E'(\zeta) = -g_B B/2 \) from which \( (\partial \zeta/\partial B)_{B=0} = -(g_B B/2)/E''(0) \) immediately follows. An estimate of the spin susceptibility can be thus obtained from the knowledge of the internal energy \( E(\zeta) \).

The effect of thickness on the 2DEG can be cast, in the simplest approximation, in terms of a device specific form factor \( F(q) \) modifying in Fourier space the 2D electron-electron interaction \( v(q) = 2\pi e^2/\epsilon q \) into \( \tilde{v}(q) = v(q)F(q) \). Rather than performing new simulations for each device we have estimated the effects of thickness on \( E(\zeta) \) and hence on \( \chi_s \) in a straightforward manner resorting to perturbation theory. In fact, to the lowest order in \( \Delta v(r) = \tilde{v}(r) - v(r) \), one has for the energy per particle \( E(\zeta) = E_{2D}(\zeta) + \Delta(\zeta) \),

\[
\Delta(\zeta) = \frac{n}{2} \int dr \Delta v(r) [g_{2D}(\zeta; r) - 1],
\]

with \( E_{2D}(\zeta) \) and \( g_{2D}(\zeta; r) \) the known energy and pair correlation function, respectively, of the strictly 2D electron gas. The accuracy of the energy estimates obtained in such a manner has been checked a posteriori performing selected simulations with the interaction \( \tilde{v}(r) \). We have computed the effect of thickness in two cases, for a GaAs HIGFET and for an AlAs quantum well (QW). In the first case the form factor is

\[
F(q) = [1 + \frac{9q}{8b} + \frac{9q^2}{8b^2}][1 + \frac{9}{b^2}]^{-3},
\]

with \( b^3 = 48\pi m_0 e^2 n^*/\hbar^2 \) and \( n^* = n_d + \frac{11}{32} n \). Here, \( n_d \) is the depletion charge density in the device, \( m_b = 0.067m_0 \) the band electron mass and \( \epsilon = 12.9 \) the average background dielectric constant. For the AlAs QW, on the other hand, the form factor can be written as

\[
F(q) = \frac{1}{4\pi^2 + q^2 a^2} \left( 3qa + \frac{8\pi^2}{qa} - \frac{32\pi^4}{a^2} \frac{1 - e^{-qa}}{4\pi^2 + q^2 a^2} \right).
\]
with \( a = 45 \text{Å} \) the width of the well\[10\]. Once \( F(q) \) is known, it is a simple matter to evaluate \( \Delta(\zeta) \), using Eq. \( 1 \), from which the enhancement \( \chi_s/\chi_P \) of the spin susceptibility \( \chi_s \) on its independent-particle or Pauli value \( \chi_P \) is immediately obtained as \( E_0(0)/E''(0) \), with \( E_0(\zeta) = E_F(1 + \zeta^2)/2 \) the energy per particle of non-interacting Fermions in 2D and \( E_F \) the Fermi energy. Thus

\[
\frac{\chi_s}{\chi_P} = \frac{E_F}{E''(0)}. \tag{4}
\]

Our main findings\[20\] are summarized in Figure \( 1 \) which shows a number of calculations and measurements of \( \chi_s/\chi_P \). This quantity is plotted against the 2D coupling parameter \( r_s = U/E_F = 1/\sqrt{\pi a_B} \) to get rid of uninteresting details of different materials which simply determine the effective Bohr radius \( a_B = \hbar^2/ma_b \) through the dielectric constant \( \epsilon \) and band mass \( m_b \); above, \( U = e^2/\sqrt{\pi}\alpha/\epsilon \) denotes a rough estimate of the potential energy per particle and \( E_F = \hbar^2\pi n/m_b \).

The QMC prediction for the strictly 2D case\[13\] (thick solid line), is between 30% and 50% off the experimental values for GaAs (thick dotted line). The key result of this paper is that this significant discrepancy is quantitatively explained as an effect of finite thickness, as clearly shown by the thin dotted line, obtained via Eqs. \( 1, 2, 4 \). This conclusion is further strengthened by our explicit estimate of the effect of weak disorder, due to background doping in the GaAs HIGFET\[9\], which turns out to be negligible (see below). We emphasize that the parameters entering the form factor of Eq. \( 2 \) reflect our knowledge of the real sample\[15\], and they are not adjusted to achieve a particular value of the spin susceptibility.

In view of the interest for a possible ferromagnetic instability in low-density 2D electron systems, the question arises as to whether thickness, which noticeably changes the spin susceptibility, also alters the stability range of the polarized fluid (26 \( \lesssim r_s \lesssim 35 \)) predicted by QMC in the strictly 2D case\[13\]. Figure \( 2 \) shows that this stability window is only slightly shrunk (by \( \lesssim 2 \) in \( r_s \)) and the ferromagnetic instability pushed at slightly higher \( r_s \).

For the AlAs device the situation is somewhat different. In order to engineer a one–valley 2DEG with isotropic mass, the electrons are confined in a very narrow QW, thus reducing the importance of finite thickness effects, but also boosting the possible influence of well width fluctuations\[10\]. The spin susceptibility, measured with either the tilted field or the polarization field methods (filled and empty symbols in Fig. \( 1 \) respectively), turns out to be fairly close to the strictly 2D QMC value. As expected, the tiny width of the QW does not affect this value significantly, as shown by the thick and the thin full curves in Fig. \( 1 \). Therefore the small discrepancy between the QMC prediction (with or without finite thickness) and the experimental result points to a possible role of disorder.

Before discussing our estimates of the effect of disorder, however, it is worth to briefly comment on the two different techniques used to measure \( \chi_s/\chi_P \). Within the Landau–Fermi liquid theory, the susceptibility enhancement can be expressed in terms of the quasiparticle parameters \( g^* \) and \( m^* \) as \( \chi_s/\chi_P = g^*m^*/g_b m_b \), where \( m_b \) and \( g_b \) are the mass and g-factor entering the hamiltonian describing the interacting electrons, which for electrons in
a device coincide with the band mass and g-factor. One of the experimental techniques employed to estimate $\chi_s$ is the tilted field method of Fang and Stiles \[21\], which allows the determination of $g^*m^*$ from the analysis of the minima in the Shubnikov-de Haas oscillations. The experimental results in Fig. 4 for the HIGFET and part of those for the QW's (full symbols) were obtained with this technique. An alternative manner to extract $g^*m^*$ from experiments has been suggested by Okamoto \[4\]. If the interacting electrons can be replaced by independent particles with effective parameters ($m^*$ and $g^*$), then the (in–plane) magnetic field necessary to induce full spin polarization satisfies $\mu_B g^* B_P = 2E_F = h^2 2\pi n/m^*$, which gives $\chi_s/\chi_P = 2E_F/\mu_B m b B_P$. However, the (in–plane) polarization must also satisfy the exact condition $\mu_B B_P = 2E'\langle 1 \rangle$, which combined with the above yields

$$\frac{\chi_s}{\chi_P} = \frac{E_F}{E'}\langle 1 \rangle.$$  \hspace{1cm} \text{(5)}$$

The experimental results for the AlAs QW’s obtained with both techniques are consistent with each other, due to the spread in the data. On the other hand, this is not the case with QMC \[13\] for which Eq. \[6\] yields an appreciable overestimate of the susceptibility enhancement. While the correct definition of the spin susceptibility is the one of Eq. \[4\], in comparing measured and calculated values of $\chi_s/\chi_P$ it is appropriate to refer to theoretical estimates consistent with the adopted experimental determination. In particular for low density, where only polarization field data are available (say $r_s$ larger than about 6), the theoretical value to be considered is the dash-dotted lines, calculated using Eq. \[5\].

We now turn to the discussion of the disorder effects. A realistic description of these devices needs the inclusion of the different scattering sources that determine the mobility at zero temperature. The GaAs HIGFET \[11\] is a very clean device with no intentional doping and with a concentration of background impurities of $\approx 5 \times 10^{12} \text{cm}^{-3}$, which is indeed a very low value \[22\]. Such a concentration has obtained through a best fit of the measured mobility \[22\], as a function of the electron density, computed using Born approximation \[24\]. We estimate the gross effect of such weak disorder on the spin susceptibility by means of perturbation theory, describing the disorder in terms of an external one-body potential $u(r)$, coupling to the electron density, with known first and second moment ensemble averages \[22\]. As usual we assume a vanishing first moment. The first non vanishing contribution to the energy reads:

$$\Delta_d(\zeta) = \frac{1}{2n} \int \frac{d\mathbf{q}}{(2\pi)^2} \chi_{n,n}(q,\zeta) \frac{(u(\mathbf{q}))^2}{A},$$  \hspace{1cm} \text{(6)}$$

with $u(\mathbf{q})$ the 2D Fourier transform of the one-body potential and $\langle \cdots \rangle$ denoting the ensemble average over disorder configurations, per unit area. Above, $\chi_{n,n}(q,\zeta)$ is the density–density response function (in Fourier space) at polarization $\zeta$ for the strictly 2DEG \[24\].

In Fig. 3 we show our results for the GaAs HIGFET, using Eq. \[6\] to estimate the effect of disorder in a density range in which $\Delta_d(\zeta)$ is much smaller (less than 1%) than the unperturbed 2DEG energy. The effect of disorder is to enhance the spin susceptibility, contrary to that of transverse thickness. However, in the experimental density range ($3 \lesssim r_s \lesssim 8$) such an effect is negligible.

The mobility in AlAs QW’s is roughly two orders of magnitude smaller than in the GaAs HIGFET, as the scattering sources are more effective. We were able to reproduce the measured mobilities \[10\], using Born approximation \[24\], only up to $r_s \lesssim 4$. In this density range the additional enhancement of $\chi_s$ due to disorder remains $\lesssim 10\%$, yielding a good agreement between the prediction of Eq. \[6\], with $\Delta(\zeta) = E_{2D}(\zeta) + \Delta_d(\zeta)$, and the available results of the tilted field experiments. Our findings suggest that, far from the metal-insulator transition, occurring at $r_s^c = 8.3$ in AlAs QW’s and at $r_s^c = 12.4$ in the GaAs HIGFET, disorder effects yield a small enhancement of $\chi_s$, which is either negligible as in GaAs or helps in reducing the small residual discrepancy between QMC and experiments. However, to obtain indications valid at larger $r_s$ and/or stronger disorder, an approach that takes into account disorder and electron-electron interaction on the same footing is required.

We finally comment on the two–valley electron system, realized in Si MOSFETs \[4, 5, 6, 7\] and in wide AlAs QW’s \[11\]. In particular Shkolnikov et al \[11\], tuning the valley population, have shown that valley degeneracy brings about a depression of the spin susceptibility, in sharp qualitative contrast with the enhance-
ment predicted by Hartree-Fock theory. A first estimate of the spin susceptibility of a two–valley symmetric EG can be simply obtained from previous QMC studies of the energy of four–electron performed with the same level of accuracy, assuming a quadratic dispersion of the energy $E(\zeta)$ with $\zeta$. Such an estimate clearly shows the qualitative effect observed in Ref. 11. A detailed comparison with either the Si MOSFET, the anisotropic–mass AlAs QW devices along the lines of the present calculation would require QMC input which is presently not available.

In conclusion we have shown that a realistic description of actual devices, starting from the 2DEG model and including specific features of the systems, enables us to reproduce the spin susceptibility without any adjustable parameters. In GaAs HIGFET the thickness plays a crucial role, while the weak disorder provides only a negligibly small enhancement. In the AlAs QW’s case the strictly 2D two–valley system with finite polarization can be simply obtained from previous QMC studies and exploit the fact that Eq. (3c) of [19] has misprints.

Evidently, one has to calculate the EG properties for a given configuration of disorder and then average the properties on disorder configurations (ensemble average).

We include disorder parameters for the real device(K. Vakili private communication), adjusting only the parameters for the QW width fluctuations (roughness scattering) to obtain agreement with the measured mobility. After the considered HIGFET the depletion is negligible (H. Stormer private communication) and we set $n_d = 0$.

We refer the reader to [30] for the description of disorder in GaAs Heterostructures and to [12] for QW’s, noting that Eq. (3c) of [12] has misprints.

Evidently, if $E_{1v}(\zeta)$ and $E_{2v}(\zeta)$ are the energy of the two-component (spin degeneracy) and four-component (spin and valley degeneracy) systems, we set $E_{2v}(\zeta) \approx E_{2v}(0) + (E_{2v}(1) - E_{2v}(0))\zeta^2$ and exploit the fact that for symmetric valleys $E_{2v}(1) = E_{1v}(0)$.
