INTRODUCTION

Turner syndrome is one of the most common forms of chromosomal aneuploidy. The majority of cases (~45%) are characterised by sex chromosome monosomy (45,X),\(^1\) with the remaining cases caused by a structurally abnormal X-chromosome or mosaicism. Turner syndrome is associated with prenatal lethality, with ~98% of 45,X conceptuses spontaneously aborting.\(^2\) The clinical phenotype is variable and can be subtle, although it most commonly presents with short stature and primary amenorrhoea (60–90% cases).\(^3\) More variable features include congenital lymphoedema of the hands and feet (see Figure 1), distinct craniofacial features (including a low posterior hairline and low-set ears), physical malformations (including a webbed neck (see Figure 1) and widely spaced nipples), cardiovascular (50% of patients),\(^4\) thyroid and renal complications (~39% patients),\(^5\) socio-behavioural difficulties and gonadal dysgenesis (from which amenorrhoea and infertility often result).\(^3,5–8\)

Lymphoedema is a chronic, debilitating and incurable condition. It is characterised by the accumulation of lymph and other elements (commonly proteins) in the interstitial spaces. This is due to a failure of the lymph-conducting system. A compromised lymphatic system results in lymphatic insufficiency, with swelling and fluid retention in one or more limbs or body segment (eg, head, neck or genitalia) or systemically with gut, pericardial or respiratory involvement. Primary lymphoedema has many genetic causes.\(^9\) Like Turner syndrome, Milroy disease may present with congenital pedal oedema; however, hand swelling is rarely noted in Milroy disease and this condition affects males and females equally.\(^10\) Lymphoscintigraphy (imaging of peripheral lymph drainage through interstitial injection of a radiolabelled colloid and gamma camera detection) is the gold-standard investigation for lymphoedema, but it is not routinely performed in all centres.\(^11\)

Lymphoedema of the hands and feet is thought to be present in >60% of infants with Turner syndrome. This facilitates an early diagnosis in an approximately one-third of patients.\(^2\) Swollen hands and feet in a female neonate always suggest a diagnosis of Turner syndrome.\(^2\) Lymphoedema is thought to result from lymphatic hypoplasia or aplasia of the lymphatic tracts, which results in stasis of lymph fluid and swelling.\(^2,5,12\) Many phenotypic features of Turner syndrome are believed to result from in utero oedema.\(^2\) Cervical lymphatic system distension manifests as a webbed neck and a low posterior hairline\(^2\) (observable as increased nuchal translucency on ultrasound scanning (US)) at 10–14 weeks\(^8,12\). In utero facial oedema manifests as epicantic folds and peripheral lymphoedema manifests as swollen hands and feet, deep digital skin fold creases and small dysplastic toenails. Prenatal lethality in Turner syndrome may also be due to an underlying lymphatic abnormality, resulting in fluid imbalance and hydrops fetalis.\(^13\)

There is a lack of detailed medical literature regarding the lymphatic phenotype of Turner syndrome. The literature that is available reports that lymphoedema is most commonly found in Turner syndrome patients with a non-mosaic 45,X karyotype and usually resolves by 2 years of age, although it can persist throughout life and recur.\(^2,14,15\) One key study, a retrospective questionnaire study focusing on the progression of lymphoedema in 42 Turner syndrome patients, found that 76% patients had swelling at birth and 55% had hand and feet swelling. Swelling resolved in 19% (87% of these by 2 years), improved in 31%, worsened in 10% and was unchanged in 40%.\(^16\) One lymphoscintigraphic study of Turner syndrome patients has demonstrated various lymphatic pathological features and identified...
aplasia, hypoplasia and hyperplasia of the peripheral lymphatics in Turner syndrome patients.\textsuperscript{17}

Identification of causative genes for the lymphatic phenotype in Turner syndrome has proven difficult. To date, only one gene, short-stature homeobox gene (SHOX), has been confirmed to cause phenotypic features of Turner syndrome, specifically short stature and skeletal abnormalities.\textsuperscript{18,19} The lymphatic phenotype in Turner syndrome is thought to be due to haploinsufficiency of an X/Y

homologous putative lymphogenic gene, other than the SHOX gene, that escapes X inactivation.\textsuperscript{18,19} Two ‘critical regions’ for the lymphogenic gene have been proposed at chromosomal regions Xp11.4\textsuperscript{18} and Yp11.2,\textsuperscript{20} but no specific genes have been confirmed.

The diagnosis and treatment of lymphoedema are as it is for any primary lymphoedema, namely Decongestive Lymphatic Therapy (DLT),\textsuperscript{21} but the lymphatic phenotype in Turner syndrome has specific idiosyncrasies, which are not widely reported in the literature. This study aims to elucidate the key features of the lymphatic phenotype in Turner syndrome and provide vital insights into its diagnosis, natural history and management.

**MATERIALS AND METHODS**

**Study subjects**

Patients were recruited and seen at three specialist primary lymphoedema clinics at St George’s Hospital (London), the Royal Derby Hospital (Derby) and Queen’s Medical Centre (Nottingham). The study cohort consisted of 19 female patients all of whom had confirmed Turner syndrome: 18 had a karyotype report available and one did not have a formal karyotype report available but their medical records clearly and consistently document a diagnosis of Turner syndrome. All 19 patients had lymphoedema on clinical inspection at their corresponding clinics. The study sample was ascertained at each clinic by identifying all patients with Turner syndrome and lymphoedema from hospital databases.

**Clinical data**

Clinical data were collected from patient notes, genetic notes, electronic records and imaging records (specifically lymphoscintigraphy reports) and located by the use of patient-specific numerical identifiers. All notes were thoroughly analysed and examined and any important information was inserted into a spreadsheet pro forma. A thorough documentation of each patient’s demographics, history of Turner syndrome and history of lymphoedema was performed. All patients were examined by at least one of the authors (PM, VK, KG, SM and GWB). Ethical approval was covered by the ‘Analysis of genes and their functions in patients with primary lymphoedema’ study, REC Reference: 05/Q0803/267.

**Lymphoscintigraphy**

Lymphoscintigraphy scan images or reports were obtained for those patients who had undergone the investigation. Scan images were reported blind with no knowledge of clinical details. An attempt was made to interpret the lymphatic fault to determine whether there was a consistent mechanism to explain the lymphoedema.

**RESULTS**

**Demographics**

The mean age and age range of the study cohort were 16.0 years (SD ±13.13 years) and 2–45 years, respectively (see Table 1). The ethnic origin of 16 patients was classed as ‘White British’, 2 as ‘any other white background (white)’ and 1 as ‘any other mixed background (black)’.

**Clinical data**

Table 1 provides summary information for the age, karyotype, age of onset, natural history, systemic involvement and the complications from lymphoedema for each patient.

**Turner syndrome history**

Seventy-nine percent (15/19) of patients were diagnosed with Turner syndrome postnatally. The majority of these patients had suspected Turner syndrome at birth owing to swollen hands and feet, although two patients were diagnosed at a later age (14 and 19 years). The remaining 21% (4/19) were diagnosed prenatally, initially suspected owing to an increased nuchal translucency on USS and confirmed by

amniocentesis. Eighty-nine percent (17/19) of patients had a 45,X karyotype, 5% (1/19) of patients had mosaic Turner syndrome and one karyotype was unattainable.

**Natural history of lymphoedema**

Ninety-five percent (18/19) of the patients presented with four-limb swelling at birth. Lymphoedema was persistent for most individuals throughout life with 15 of the 19 patients (79%) having persistent lymphoedema in at least one limb. In 63% (12/19) of patients, the swelling improved over time and of these, 33% (4/12) had swelling that completely resolved at a young age (<4 years) but later recurred in at least one limb. One patient (5%) developed lymphoedema for the first time at the age of 10 years old. One patient (5%) presented with suspected systemic disease, intestinal lymphangiectasia, but this was not confirmed. There was no evidence of any facial or genital swelling. Five of the patients (26%) suffered from cellulitis (two of them had recurrent infections), a common complication of lymphoedema. The lymphatic phenotype of two patients is shown in Figure 1.

**Lymphoscintigraphy results**

Lymphoscintigraphy had been performed on six patients with clinically identifiable lymphoedema. Written lymphoscintigraphy reports were available for all six patients. The lymphoscintigram images for one patient were unavailable and our own interpretation of these images was, therefore, not possible in this case. The available lymphoscintigram images for five patients showed similarities, namely a failure of tracer uptake and absorption into the lymph system with retention of the bulk of tracer at the site of injection after 2 h. Figure 2 documents the quantitative lymphoscintigraphy values. As a result of poor uptake of tracer into the lymphatic system, there was reduced imaging of downstream drainage channels and lymph nodes in most cases (see Figure 2). These features suggest a failure of initial lymphatic (capillary) function.

**Management**

Table 1 summarises the management for each patient. The treatment given was largely proportional to the severity of lymphoedema: from skin and nail care in less severe cases to compression stockings, manual lymph drainage and DLT in more severe cases. Compression garments were the mainstay of treatment for this cohort of patients.

**DISCUSSION**

Almost all patients in this study presented with four-limb swelling at birth. The majority had lymphoedema persisting throughout life. This corroborates what is already well documented in the literature. In four patients, the swelling completely resolved but recurred in at least one limb. This recurrence has been described in Turner syndrome patients before,\textsuperscript{2,14,15} but it is a phenomenon that is poorly documented and described. In two of these four patients, the lymphoedema resolved in early infancy. In the remaining two patients it resolved in early childhood. The timescale of recurrence was variable, ranging from 8.5 to ~40 years between the initial resolution and recurrence. The site of recurrence was also variable (see Table 1). The results of this study also indicate that systemic lymphatic involvement is a rare feature of the Turner phenotype with only one patient presenting with suspected (but not proven) intestinal lymphangiectasia. Interestingly, only one of the patients had a mosaic form of Turner syndrome. The majority had 45,X in all cells examined.

The most significant discovery from this study was the consistent abnormality observed on the lymphoscintigraphy images. The images suggested that the lymphatic abnormality in Turner syndrome is due
to a failure of lymph absorption by the initial lymphatic capillaries. Biopsy studies would be required to determine whether there is an anatomical reduction in the number of initial lymphatic vessels or whether these initial vessels are present in normal numbers but are dysfunctional. The fact that lymphoedema can resolve would suggest a functional rather than a structural mechanism. A functional failure of lymph uptake and transport by initial lymphatics is the proven mechanism in Milroy disease where the causal mutation is in \textit{FLT4} (the gene for vascular endothelial growth factor receptor 3, VEGFR3\textsuperscript{22}). The upper limbs are rarely involved in Milroy disease.\textsuperscript{23} The lymphoscintigraphic manifestation of Turner syndrome has been described once before in a study of 18 Turner syndrome patients.\textsuperscript{17}

| Qualitative Lymphoscintigraphy | Quantitative Lymphoscintigraphy | Qualitative Lymphoscintigraphy | Quantitative Lymphoscintigraphy |

European Journal of Human Genetics
where 15 showed an abnormal lymphoscintigraphic pattern, but there was no quantification relating to initial lymphatic function. Furthermore, only four of the 15 patients had clinically identifiable lymphoedema at some stage in their lives. Hypoplasia was the dominant lymphatic impairment demonstrated in their cohort. Our study identified initial lymphatic failure as the dominant pattern of lymphatic system impairment in all five patients with clinically identifiable lymphoedema and available lymphoscintigrams.

There is ascertainment bias in this observational study, as only patients being followed up in the lymphoedema clinics were considered.

We can conclude that Turner syndrome frequently presents at birth with four-limb lymphoedema, which often resolves to a certain degree in early childhood but may recur at any age. There is rarely systemic involvement or swelling of the face, trunk or genitalia. The lymphoscintigraphy results suggest that the mechanism for lymphoedema in Turner syndrome is a failure of initial lymphatic function.

Future work could involve a prospective study of patients with Turner syndrome presenting at birth to look at the natural history of lymphoedema with further investigation of Turner syndrome patients with and without lymphoedema.

CONFLICT OF INTEREST

The authors declare no conflict of interest.
