We compute the crossover exponents of all quadratic and cubic deformations of critical field theories with permutation symmetry S_q in d = 6 − ϵ (Landau-Potts field theories) and d = 4 − ϵ (hypertetrahedral models) up to three loops. We use our results to determine the ϵ-expansion of the fractal dimension of critical clusters in the most interesting cases, which include spanning trees and forests (q → 0), and bond percolations (q → 1). We also explicitly verify several expected degeneracies in the spectrum of relevant operators for natural values of q upon analytic continuation, which are linked to logarithmic corrections of CFT correlators, and use the ϵ-expansion to determine the universal coefficients of such logarithms.

I. INTRODUCTION

The lattice Potts model can be seen as a generalization of the simple ferromagnetic Ising model at zero magnetic field, in which the two possible spin states, up and down, are replaced by q distinct states which interact locally through a term that favors the same state between neighboring sites. By construction, the Potts model is invariant under the permutation group S_q of the states, which recovers the symmetry of the Ising model for q = 2 when, in fact, S_2 ≃ Z_2. The similarity with the Ising model goes further, in that, depending on the number of states and on the dimensionality of the system, also the Potts model exhibits a critical point which can be reached by tuning the temperature [2]. At the critical point the correlation length diverges and the properties of the system are governed by critical exponents. The computation of critical exponents for the q-states Potts model at criticality goes almost as far back as the same computation for the Ising and O(N) models.

Critical exponents can be computed by means of the standard ϵ-expansion in field theory. There is a minor caveat here, because the analysis of a S_q invariant theory requires the construction of a Landau-Ginzburg ϕ^3-like interaction (to be compared with ϕ^4-like for the Ising and O(N) models), which in turn implies that the ϵ-expansion should be constructed below the critical dimension d_c = 6 [4], implying that the model has non-mean-field exponents also in d = 4−5 [5,6]. This has the consequence that the ϵ-expansion converges poorly, especially when one is interested in estimates in lower dimensions such as d = 2,3 [7,9]. For the same reason, it is still very much unknown the precise form of the phase diagram of existence of a non-trivial critical point for the Potts model in the (q,d) plane [9,10]. Nevertheless the ϵ-expansion offers a solid ground which is very reliable when approaching the regions of small ϵ for obvious reasons, so the method has been developed to the fourth order [11,12].

Traditionally, critical points for ϕ^n theories with continuous and discrete symmetries, such as the ones mentioned above, are mostly approached by tuning the temperature but maintaining the symmetry. This can be conveniently implemented with functional perturbative renormalization group methods [15–19]. The exception to the previous statement is, of course, the inclusion of a magnetic field which in the Ising and O(N) models magnetizes the system, while in the Potts model promotes one or more states over the others. A magnetic field breaks S_q symmetry and drives the system to an Ising-like Z_2 phase [20]. In the field theory framework, the magnetic deformation of the system corresponds to adding a linear term in the field(s) h · ϕ, having denoted h the magnetic field. There are, however, very many other ways to break explicitly the symmetry group of the system other than including the magnetic field. The simplest ones, which are also relevant in the sense of the renormalization group (RG), are arbitrary non-singlet deformations which are quadratic and cubic in the field(s) ϕ [21–23].

The non-singlet deformations are important for several reasons. On the one hand, they can be linked for some models to interesting observables, and therefore are worth studying [21–23]. On the other hand, it is possible to imagine situations in which the temperature T is tuned to its critical value T_c, but the system is deformed by a non-singlet interaction in the Hamiltonian. In this case, one can expect that the system exhibits critical behavior for this interaction going to zero, which is in fact what happens [25–28]. The new critical behavior is governed by so-called crossover exponents, because non-singlet deformations drive the system to a phase with different symmetry, and therefore at criticality the system crosses over two different phases. A very simple example of critical crossover can be observed by giving a nonzero mass square m^2 to k < N fields of th O(N) model: the symmetry group is broken down to a subgroup and if we take m^2 → 0 for T ≤ T_c there is a second order line

\[ m^2 \rightarrow 0 \quad \text{for} \quad T \leq T_c \]
separating \( O(k) \) and \( O(N - k) \) phases \[29, 31\].

The fact that non-singlet deformations are not scalars under the action of the group does not imply that they have nothing to do with the group itself. Using representation theory it is possible to decompose any product of representations composing the general deformation in terms of irreducible representations \[21, 23\], even though, as we shall see later in section \[11\] the application of this method is complicated by the presence of mixing between vector currents. One interesting fact is that for almost all values of the parameters \( q \) the irreducibly decomposed operators are also scaling operators from the point of view of the renormalization group, implying that the action of the dilatation operator commutes with the action of the symmetry group. Even more interesting are the countable cases in which this commutation is not quite true: in these cases the nondiagonalizable action of the dilatation is seen as a Jordan cell from the point of view of the underlying conformal field theory (CFT) \[32\], which leads to logarithmic contributions in the critical correlators and logarithmic CFTs (log-CFTs) \[21, 33–35\] that have been observed numerically \[36–39\] (see \[40\] for a recent review, and see \[11\] for an introductory discussion of log-CFTs from the point of view of the renormalization group in the context of randomly diluted models).

One way to understand these logarithms goes as follows: for some value \( q = q_c \), the scaling dimensions of two or more operators approach the same value and can be linearly combined into their would-be analog at \( q_c \) and a logarithmic partner. This combination happens precisely for those values \( q_c \) in which the operators cannot be distinguished on the basis of symmetry \[21\]. For example, if we are considering the \( 3 \)-states Potts model, the operator that measures (the propagation of) four distinct clusters of states cannot be distinguished from the one that measures (the propagation of) three clusters of states. In this case one can expect that the scaling dimension of the three and four cluster operators coincide in the limit \( q \to 3 \), and this is precisely what happens. The operator measuring four clusters is lost in the limit, but a new one emerges which has logarithms in its two- and higher point functions. The construction of observables that are actually capable of evidencing the logarithmic behavior in the correlation is a whole new problem \[37, 39\]. Insofar, a well-crafted observable has been proposed and measured for the case \( q \to 1 \) \[22, 24\], and is known to be relevant for the universality class to which (bond) percolations belong \[42, 43\]. We argue, however, that similar observables can be constructed for arbitrary values of \( q \) making room to several possible new numerical investigations of logarithmic critical behaviors \[37, 39\].

Having mentioned the case of the percolations, it is worth discussing some further point which are relevant for few special values of \( q \). Following literally the discussion on permutation invariance, the only values of \( q \) allowed are the integers bigger than or equal to two. Using a representation due to Fortuin-Kasteleyn \[44\], it is however possible to rewrite the partition function of the lattice Potts model in such a way that it makes sense for arbitrary (continuous) values of \( q \). On a similar note, it is possible to show that the limit \( q \to 1 \) coincides with the model of bond percolations, and thus at criticality covers the corresponding universality class \[45\], which remains a conformal field theory \[46\]. Another interesting limit is the one for \( q \to 0 \), which is known to correspond to a model of random clusters describing spanning trees and forests (depending on how the limit is taken \[47–49\]. On the field theory side, the above two limits are not straightforwardly accessible from the point of view of the degrees of freedom (they would correspond to having either no fields, or a negative number). Even though there are mechanisms to create the appropriate number of fields using fermions \[50\], and thus describe the correct physics, the simplest option is to just compute any physical quantity (such as critical exponents) as a function of \( q \) and take the limits \( q \to 0 \) and \( q \to 1 \) at the end. In this sense, the limit \( q \to 1 \) of the field theory is known to represent the universality class of percolations, while \( q \to 0 \) is believed to represent the universality class of spanning forests and trees.

The interesting part of how clusters (including bond percolations, trees and forests) are generated through the Fortuin-Kasteleyn representation \[44\] is that they live in the links connecting the lattice sites. One can argue that the clusters live in the same space in which propagator lines of the field theory would live. This connection becomes even more interesting if complemented with the notion, recently discussed for the \( O(N) \) model by Kompagnets and Wiese \[31\], that the inverse of the scaling exponents of a specific quadratic operator is the fractal dimension of propagator lines. In the case of the \( q \)-states Potts model, representation theory shows that there are other two operators besides the singlet, a vector and a tensor, which can both be associated to a certain notion of fractal dimension \[51–52\]. The vector gives the fractal dimension of propagator lines just as in \[31\], the tensor gives a fractal dimension of the cluster interpreted as a network of resistances \[53–56\].

In this paper, we give estimates of non-singlet scaling exponents, crossover exponents, and some further universal quantity relevant for log-CFT for the \( q \)-states Landau-Potts field theory in \( d = 6 - \epsilon \) using the renormalization group to three loops \[10\]. Our result extends the previous literature \[25–28\] by streamlining the computation, thanks to a careful use of the representation theory of \( S_q \), and including one further order in the perturbative expansion. We also briefly discuss the same quantities for a sibling model known as the hypertetrahedral model in \( d = 4 - \epsilon \), again up to three loops, which, to the best of our knowledge, was never presented elsewhere. Our results are used to compute several quantities of interest, but we pay particular attention to crossover exponents and universal log-CFT data. The paper is organized to give a brief (certainly inexhaustive) introduction to most of the topics that we touched in this introduction. In Sect. \[11\] we show how to construct general Landau-Ginzburg-like
field theories with permutation symmetry; in Sect. III we discuss the irreducible representations that emerge for quadratic and cubic deformations; in Sect. IV we discuss how crossover exponents appear at criticality; in Sect. V we discuss the relation with log-CFT and several special limits; in Sects. VI and VIII we give our main results for the cases $d = 6 - \epsilon$ and $d = 4 - \epsilon$ respectively.

II. LANDAU-POTTS FIELD THEORIES

The construction of a field theory which is manifestly invariant under $S_q$ symmetry conveniently starts by introducing a set $e^\alpha$ of $q$ vectors ($\alpha = 1, \cdots, q$) in $\mathbb{R}^N$ with $N = q - 1$ forming the vertices of a regular $N$-symplex (hypertetrahedron) \cite{ref37}. The group $S_q$ then acts by permuting vertices of the symplex, while the vertices represent the possible states of the model. For obvious reasons, throughout this construction, we assume that $q$ takes values in $\mathbb{N}$ and $q > 1$, although the most interesting applications will come from analytic continuation outside this domain \cite{ref43}. We normalize the vertices as

\begin{align}
\sum_{i=1}^N e^\alpha_i e^\beta_i &= q \delta^{\alpha\beta} - 1, \\
\sum_{\alpha=1}^q e^\alpha_i &= 0, \\
\sum_{\alpha=1}^q e^\alpha_i e^\beta_j &= q \delta_{ij}.
\end{align}

Basic covariant tensors with respect to the permutation symmetry can be constructed as sums of $n$ vertices

\begin{equation}
Q^{(n)}_{ij\cdots k} = \sum_{\alpha=1}^q e^\alpha_i e^\alpha_j \cdots e^\alpha_k,
\end{equation}

which obviously implies that $Q^{(2)}_{ij} = q \delta_{ij}$ and $Q^{(1)} = 0$, but all other tensors are not as easily determined for arbitrary values of $q$. Since permutations act on the Greek indices $\alpha$, any sum over a Greek index is automatically invariant.

The general $S_q$ covariant order parameter is defined as the linear combination vector $\psi^\alpha = \sum_{i=1}^N e^\alpha_i \varphi_i$ and therefore has $N$ independent components $\varphi_i$ which play the role of fields. Notice that the covariance of $\psi$ under $S_q$ induces a corresponding transformation on the multiplet $\varphi_i$, which we refer to as the vector representation of $S_q$. Since the action on $\varphi_i$ is by construction an element of $O(N)$, it underlies the fact that $S_q = S_{N+1}$ is a subgroup of $O(N)$ \cite{ref17}. By construction, an arbitrary scalar potential $V(\psi)$, which is a function of $\psi^\alpha$, is also invariant under the permutation group if it is summed over the state’s index $\alpha$. Consequently, inserting the explicit form of $\psi^\alpha$, it is always possible to express any potential as the sum of products of the tensors $Q^{(n)}$ and the basic fields $\varphi_i$ and determine the explicit form of the action of the permutation group.

In $d = 6 - \epsilon$ dimensions the perturbatively renormalizable Landau-Potts field theory has potential

\begin{equation}
V(\psi) = \frac{\lambda}{3!} \sum_{\alpha} (\psi^\alpha)^3 = \frac{\lambda}{6} \sum_{ijk} Q^{(3)}_{ijk} \varphi_i \varphi_j \varphi_k,
\end{equation}

which could be deformed by additional relevant operators that we analyze more carefully in the next section. The cubic potential ensures perturbative renormalizability in $d = 6$ dimensions if complemented by the standard kinetic term for the fields $\varphi_i$. This can be seen from simple power-counting, which tells us that the coupling $\lambda$ is dimensionless in $d = 6$. Notice that, for $q = 2$, it is easy to see that, by construction, $V(\psi) = 0$: this happens because the 2-states Potts model is just a redefinition of the Ising universality class, which in $d = 6 - \epsilon$ is above the upper critical dimension.

In $d = 4 - \epsilon$ dimensions the perturbatively renormalizable Landau-Potts field theory is referred to as the hyper-tetrahedral model and sometimes as the restricted Potts model. It can be seen as a generalization of the traditional $\phi^4$ theory of the Ising’s universality class, which thus must be recovered for $q = 2$ \cite{ref27}. The potential takes the form

\begin{equation}
V(\psi) = \frac{u}{4! q^2} \sum_{\alpha\beta} (\psi^\alpha)^2 (\psi^\beta)^2 + \frac{v}{4!} \sum_{\alpha} (\psi^\alpha)^4
= \frac{u}{24} \sum_{ij} (\varphi_i)^2 (\varphi_j)^2 + \frac{v}{24} \sum_{ij} Q^{(4)}_{ijmn} \varphi_i \varphi_j \varphi_m \varphi_n.
\end{equation}

Like in the previous example, we omitted any possible relevant terms and included only interactions which are power-counting marginal at the critical dimension. The first term of the potential is manifestly invariant under the larger group $O(N)$, which includes $S_q = S_{N+1}$ as subgroup given the identification $q = N + 1$ with the number of states, and as such has been normalized to highlight this connection; in contrast the second term represents the departure from (internal) rotational invariance. The model with quartic interaction has the additional global reflection symmetry $\varphi_i \to -\varphi_i$, which combines with the permutation symmetry to form the group $S_q \ltimes \mathbb{Z}_2$. The resulting symmetry group is such that for $N = 3$ it coincides with the symmetry group $H_3$ of a cube and therefore the analysis for $N = 3$ must give the same results as the so-called cubic model. We stress, however, that in general the hypercubic group does not coincide with the group of symmetries of the restricted model, $H_N = (\mathbb{Z}_2)^N \times S_N \neq S_{N+1} \times \mathbb{Z}_2$, so the two models are distinct for any other finite number of components $N > 3$. The case $q = 2$ (equivalently $N = 1$) is special because the two interactions of (1) coincide in the limit, so the model becomes the usual single-component $\phi^4$ of the Ising universality.

\footnote{The group $O(N)$ is also the maximal symmetry that a theory with this field content can have \cite{ref16}.}
Interesting finite limits that can be followed through analytic continuation are \( q \to 1 \), which is known for \( q \) to be related to the universality class of percolations, and \( q \to 0 \), which is argued for \( q \) to describe the universality class of special random cluster models representing spanning trees and forests [17, 19]. Both identifications are supported by CFT analysis and by numerical simulations, to different extents. Another interesting limit is \( q \to \infty \), in which the spectrum of both Landau-Potts and hypertetrahedral models approach \( q \) non-interacting copies of the corresponding single-field limit [58]. In \( d = 6 - \epsilon \), this implies, for example, that the \( S_q \) critical point of [3] becomes infinitely many independent Lee-Yang models with imaginary \( \phi^3 \) potentials [4]. The implication here is that a real fixed coupling (potential) for finite value \( q \) must transition to an purely imaginary one for some value of \( q \), and this happens at the value \( q = 10/3 \), which is a well-known fact and can lead to further specifications on the nature of the \( \epsilon \)-series [11]. In \( d = 4 - \epsilon \) the limit \( q \to \infty \) leads to infinitely many copies of the spectrum of single-field’s \( \phi^4 \). Notice that the same happens when taking the limit \( N \to \infty \) of the hypercubic model with \( H_N \) symmetry [58]. A very qualitative way to interpret this limit would be to place the spins of the discrete model realizing the symmetry (either the hypertetrahedron for \( S_q \) or the hypercube for \( H_N \)) on a sphere of fixed radius, then take the limit of the number of embedding dimensions to infinity while keeping the radius fixed. Then the spins become decoupled in the limit as the number of dimensions increase.

### III. DEFORMATIONS OF SECOND AND THIRD ORDER IN THE FIELDS

It is important to analyse all possible deformations of a critical theory and we shall see how quadratic and cubic operators present different features. In the presentation we follow in part Refs. [21, 23]. The most general relevant deformation to the potentials \( \phi^3 \) and \( \phi^4 \) with two copies of the field and no spatial derivatives is of the form \( \phi^i \phi^j \) and involves an arbitrary symmetric source at the level of potential, which has \( \frac{N(N+1)}{2} = \frac{q(q-1)}{2} \) components. Each copy of the field carries a standard representation of the permutation group, and we can diagonalize the arbitrary quadratic deformation all in terms of the irreducible representations

\[
\text{Sym}_2(\mathbb{V} \otimes \mathbb{V}) = [q] \oplus [q-1,1] \oplus [q-2,2].
\]

We denoted \( S = [q] \) the singlet, \( V = [q-1,1] \) the vector, and \( T = [q-2,2] \) the symmetric 2-tensor representations, whose dimensions sum up to \( 1 + (q-1) + \frac{q(q-3)}{2} = \frac{q(q-1)}{2} \) exhausting all possible symmetric tensors with two indices.

For almost all values of \( q \), the terms of the above decomposition will also diagonalize the dilatations and therefore be scaling directions. The explicit forms of the quadratic operators are

\[
S^{(2)} = \sum_{ij} \varphi_i \varphi_j, \quad V_k^{(2)} = \sum_{ij} \varphi_i \varphi_j Q^{(3)}_{ijk},
\]

\[
T_{mn}^{(2)} = \sum_{ij} \varphi_i \varphi_j Q^{(4)}_{ijmn} - q(q-2) \varphi_m \varphi_n
\]

\[
- \frac{q}{q-1} \delta_{mn} \sum_i \varphi_i \varphi_i,
\]

in which we included an additional label 2 in between brackets to denote that they are quadratic combinations in the number of fields [3, 21].

Notice that the most general non-symmetric decomposition would include an antisymmetric 2-tensor, transforming under \( A = [q-2,1,1] \). Such tensor, however, does not contribute to the potential, because it requires at least two spatial derivatives to construct it, \( \varphi_i \partial \varphi_j \) (one if the operator is also allowed to carry spacetime spin). This notion will become relevant also in the forthcoming analysis of the cubic sector.

The most general deformation of the potential involving three copies of the field and no spatial derivatives is of the form \( \varphi_i \varphi_j \varphi_k \) and can be dealt with in a similar fashion. Using the same assumptions as the previous case, the irreducible decomposition of the product of three vector representations is

\[
\text{Sym}_3(\mathbb{V} \otimes \mathbb{V} \otimes \mathbb{V}) = [q] \oplus 2[q-1,1] \oplus [q-2,2]
\]

\[
+ [q-2,1,1] \oplus [q-3,3],
\]

corresponding to the following dimensions

\[
\frac{(q-1)q(q+1)}{6} = 1 + 2(q-1) + \frac{q(q-3)}{2}
\]

\[
+ \frac{(q-1)(q-2)}{2} + \frac{q(q-1)(q-5)}{6}.
\]

If compared with the previous example, the decomposition contains also the symmetric 3-tensor representation \( Z = [q-3,3] \). As before we neglect the antisymmetric contribution because it is not realized by our cubic deformations [23]. A partial list of the cubic operators has been discussed in [21], and, in our notation, it is given by

\[
S^{(3)} = \sum_{ijk} \varphi_i \varphi_j \varphi_k Q^{(3)}_{ijk},
\]

\[
V_k^{(3)} = \sum_{ijm} \varphi_i \varphi_j \varphi_m Q^{(4)}_{ijkm} - \frac{1}{2} \varphi_k \sum_i \varphi_i \varphi_i
\]

\[
T_{mn}^{(3)} = \sum_{ijk} \varphi_i \varphi_j \varphi_k Q^{(5)}_{ijklmn} - (q-2) \sum_{ij} \varphi_i \varphi_j \varphi_m Q^{(3)}_{nmij}
\]

\[
- \sum_{ij} \varphi_i \varphi_j \varphi Q^{(3)}_{mnij} - \frac{1}{q-1} \delta_{mn} \sum_{ijk} \varphi_i \varphi_j \varphi Q^{(3)}_{ijkl},
\]
for first three representations, and

\[ Z_{mnp}^{(3)} = \sum_{ijkmnp} \varphi_i \varphi_j \varphi_k Q_{ijkmnp}^{(6)} + \frac{(q-2)(q-3)}{2(q-1)} \sum_{rs} \varphi_r \varphi_s \varphi_m Q_{nprs}^{(4)} + [2 \text{ perms}] \]

\[ - \frac{1}{q-1} \sum_{rst} \delta_{mn} \varphi_r \varphi_s \varphi_t Q_{prst}^{(4)} + [2 \text{ perms}] \]

\[ - \frac{q-3}{q(q-1)} \sum_{rst} \varphi_r \varphi_s \varphi_t Q_{mnpr}^{(3)} Q_{psr}^{(3)} + [2 \text{ perms}] \]

\[ - \frac{2}{q(q-1)(q-2)} \sum_{rst} \varphi_r \varphi_s \varphi_t Q_{rstmnp}^{(3)} Q_{inmp}^{(3)} \]

\[ - \frac{3}{q-1} \varphi_r^2 \sum_r \varphi_i Q_{mpr}^{(4)} + \frac{q^2(q-3)(q-4)}{2(q-1)} \varphi_m \varphi_n \varphi_p \]

\[ + \frac{q^2}{2(q-1)} \delta_{mn} \varphi_p^2 \varphi_p + [2 \text{ perms}] \], \quad (10) \]

for the new one, where \( \varphi^2 = \sum_r \varphi_r \varphi_r \), “perms” refers to two more cyclic permutations of the indices \((mnp)\), and the new label \(3\) reminds us that there are three copies of the fields. The general constructed comes by iteratively removing the traces among all indices \([23]\), but let us stress that it is not complete, as further discussed in \([22]\). Moreover there can be operators which do not transform according to any representation of \(S_4\), as we discuss in Sect. \([17]\) with an explicit example.

First of all, we realize that in \([7]\) there are actually two vectors whose subspace is generated by \(\sum_{ijmn} \varphi_i \varphi_j \varphi_m Q_{ijmn}^{(4)}\) and \(\varphi_i \sum_i \varphi_i \varphi_i\), so that a mixing altering the form of \(V_3^{(3)}\) of Eq. \([9]\) is allowed. We therefore modify \(V_3^{(3)}\) to include a 2-dimensional vector space (modulo the overall normalization) by introducing an arbitrary constant \(B \neq 1\)

\[ V_3^{(3)} = \sum_{ijmn} \varphi_i \varphi_j \varphi_m Q_{ijmn}^{(4)} - \frac{B}{2} \varphi_k \sum_i \varphi_i \varphi_i. \quad (11) \]

Since the vector is constructed from two monomials, the computation of the scaling operator requires the diagonalization of a two-by-two matrix that depends on \(B\) and \(q\). This results in an equation with two solutions, \(B = B(q)\) and \(B = B'(q)\), coming from a quadratic algebraic equation for the scaling deformations.

For the Landau-Potts model the vector operators must be treated with additional care when comparing RG and CFT results. From the point of view of CFT, the operator \(V_3^{(3)}\) combines with the descendant \(\frac{\partial S}{\partial \theta}\), through the equations of motion of \([3]\), and therefore it should have scaling dimension equal to the one of the field plus two, \(\Delta_{V_3} = 2 + \Delta_\phi\). This scaling relation is replaced, in the RG context, by the more general relation involving the critical exponents \(\theta_\phi + \theta_V^{(3)} = d\), which we verify explicitly. For an arbitrary primary operator \(\mathcal{O}\) the relation between scaling dimensions and critical exponents is of course \(\Delta_{\mathcal{O}} = d - \theta_\mathcal{O}\), but it is modified for descendants. Using the relation \(\Delta_{\phi} = (d - 2 + \eta)/2\) and the above two formulas, we find that the standard relation is modified by the presence of the anomalous dimension, \(\Delta_V^{(3)} = d - \theta_V^{(3)} + \eta\).

From the physical point of view, two irreducible representations of the same rank but of different order (such as \(S^{(2)}\) and \(S^{(3)}\)) share the same \(S_4\) quantum number, but have different scaling dimensions. They can be thought to contribute different corrections to the same quantity from the point of view of statistical mechanics. For example, if we associate the quantum numbers of the singlet to the energy, then the leading nontrivial correction comes from the scaling operator \(S^{(2)}\), and the subleading correction from \(S^{(3)}\). \(2\)

IV. CROSSOVER EXPONENTS AND FRACTAL DIMENSIONS

There are two main reasons to discuss the scaling behavior of the most general quadratic and cubic operators. The first one is that, with the exception of the singlet operators, they all break the underlying permutation symmetry of the Potts field theory, and therefore they allow us to describe the crossover of the system from the symmetric critical point to a symmetry-broken phase. Under the assumption that the symmetry-broken phase has some residual (unbroken) symmetry, this implies that, close to the critical point, some crossovers to phases with smaller symmetries have associated crossover exponents. To clarify this statement, first assume that the critical point is described by a certain CFT action \(S_s\) and that, within a symmetric regime, we reach criticality by tuning the energy operator \(E\) as in \(S = S_s + g E\). We know that \(g \sim t^\nu\) which defines the critical exponent \(\nu\), following the usual scaling assumption that \(t\) is the reduced temperature \(t \sim (T - T_c)/T_c\). Now perturb \(S_s\) by a further operator \(\tilde{E}\) which breaks the symmetry in some way, \(S = S_s + g E + q_1 \tilde{E}\), and which belongs to some scaling multiplet, implying the behavior \(q_1 \sim t^\delta\) close to the critical point. Solving the two scaling relations in \(t\), we can derive how the symmetry breaking part scales with the symmetric coupling close to criticality \(q_1 \sim g^{\Phi}\), which defines the crossover exponent \(\Phi = \theta_\mathcal{E}\) of \(\mathcal{E}\).

Given a symmetry-breaking operator \(\mathcal{E}\) of interest, the only remaining point is to establish whether it actually belongs to a scaling multiplet or not. At the quadratic level the interesting operators have either one or two representation indices, implying that they can either realize a breaking in which either one or two components are selected. In the first case, corresponding to the vector

\(2\) In this language, the leading correction to the energy is actually the identity operator \(S^{(0)} = 1\), which has trivial scaling dimension \(d\) and therefore is not particularly interesting to report.
V. RELATION WITH LOG-CFTS

The second reason why we include all possible deformations has to do with the construction of logarithmic CFTs. To understand where logarithms are coming from, let us first recall that the expressions of the operators for arbitrary values of \( q \) (the number of states) are certainly redundant if \( q \) is specialized to some small values such as, for example, \( q_c = 1, 2, 3 \) etc. This redundancy implies that, by taking \( q \) equal to \( q_c \), two or more operators of Sect. [14] and of the same rank will degenerate to the same multiplet and the spectrum of the theory will encounter some form of discontinuity. The usefulness of the general approach is that we can analytically continue \( q \to q_c \), study the onset of the degeneracy, and discuss the physical implications of the two operators colliding. Rather generally, it has been shown that, given two operators \( \mathcal{X} \) and \( \mathcal{X} \) with scaling dimensions \( \Delta_\mathcal{X}(q) \) and \( \Delta_\mathcal{X}(q) \) coinciding for some value \( q = q_c \) (\( \Delta_\mathcal{X} \equiv \Delta_\mathcal{X}(q_c) = \Delta_\mathcal{X}(q_c) \)), in the limit \( q \to q_c \), the action of the dilatation operator is not appropriately diagonalized because of the appearance of a Jordan cell [34, 38, 40]. The two operators are bundled in a so-called logarithmic pair in which the usual powerlaw behavior of CFT makes room for a logarithmic term and a new universal quantity defined as

\[
\alpha_X = \lim_{q \to q_c} \frac{\Delta_X - \Delta_\mathcal{X}}{q - q_c}.
\]

A clarifying example is certainly in order, so we provide one in the rest of this section.

The simplest and, arguably, most interesting example of this situation happens for \( q = q_c = 1 \), which corresponds to the universality class of critical percolations. We follow [22], albeit with some minor notational differences, to provide an example of logarithmic pair. The role of the above operators \( X \) and \( \mathcal{X} \) is taken by the energy singlet \( E \), which has two point function

\[
(E(x)E(0)) = (q - 1) \frac{A(q)}{|x|^{2\Delta E(q)}},
\]

and by the 2-cluster operator \( \tilde{E} \), which has two point function

\[
\langle \tilde{E}_{ij}(x)\tilde{E}_{kl}(0) \rangle = \frac{2}{q^c} \left( \delta_{ik}\delta_{jl} + \delta_{ik}\delta_{jl} \right. \\
\left. - \delta_{ik} + \delta_{il} + \delta_{jk} + \delta_{jl} \right) \frac{2}{q - 2} \frac{2}{(q - 1)(q - 2)} \frac{A(q)}{|x|^{2\Delta E}},
\]

respectively. The normalizations \( A(q) \) and \( \tilde{A}(q) \) are regular functions in the vicinity of \( q = 1 \), and it is therefore evident that one correlator vanishes while the other diverges in the limit \( q \to 1 \). This singular behavior happens regardless when normalizing correlators for general \( S_q \) symmetry and it is intimately connected with the appearance of logarithms that we are about to see.

In the limit \( q \to 1 \), we have that the scaling dimensions of the two operators coincide, so we denote them \( \Delta_\mathcal{E}(1) = \Delta_{\mathcal{E}}(1) \equiv \Delta_E \) as before. A physical way to understand why something like this should happen comes from realizing that for \( q = 1 \) there cannot be an independent 2-cluster operator, because there are no two differently labelled clusters: there is only one which is the one of the percolation itself. Consistency with the two operators becoming degenerate requires that also the normalizations are related, which in this case implies that only one quantity survives the limit \( A(1) = \tilde{A}(1) \equiv A \). Let us define the universal quantity

\[
\alpha_E = \lim_{q \to 1} \frac{\Delta_\mathcal{E} - \Delta_E}{q - 1},
\]

in which we specialized the previous definition to the case \( q_c = 1 \). We define a new operator from the combination

\[
\tilde{E}_{ij}(x) \equiv \tilde{E}_{ij}(x) + \frac{2}{q(q - 1)} E(x).
\]

The new operator is meaningful in the limit \( q \to 1 \) because the singular behavior of the two terms cancels out.
To see this, one inspects the correlator and takes the limit $q \to 1$; using all the above formulas one finds

$$
\langle \hat{E}_{ij}(x) \hat{E}_{kl}(0) \rangle = 2 \left( \delta_{ik} \delta_{jl} + \delta_{ik} \delta_{jl} \right) + \delta_{tk} + \delta_{tl} + \delta_{kj} + \delta_{jl} + 4 \alpha E \log |x| \right) \frac{A}{|x|^{2\Delta}}.
$$

A very interesting aspect of this construction is that there are special observables which allow to measure the logarithmic corrections. For example, in the case of percolations, one can observe with a Monte Carlo measurement the logarithmic behavior and verify explicitly a dependence in agreement with the leading order analytic computation for $\alpha_E = \frac{\sqrt{3}}{2} \approx 0.5513$.

Contact with the operators shown in Sect. III is made using the identities $E = S$ and $E = T$, since they carry the same quantum numbers [34]. This tells us that, for the case of percolations $q = 1$, we can compute the universal quantity [14] for both the leading and subleading nontrivial contributions to the energy (respectively $S^{(2)}$ and $S^{(3)}$), thus resulting in the coefficients $\alpha^{(2)}_S$ and $\alpha^{(3)}_S$, that will be shown in the next section. In this case, it is the leading coefficient that should be compared with the lattice measure, although for obvious reasons the $\epsilon$-expansion converges poorly. For different values of $q$, there will be different Jordan cells coming from different operator degeneracies [34], which will also be discussed in the next sections.

VI. RG ESTIMATES FROM $d = 6 - \epsilon$

The renormalization group for the potential [3] can be found up to the third loop order in [16] in a dimensionally regulated scheme with minimal subtraction in $d = 6 - \epsilon$. We make use of a general theoretical framework which we call functional perturbative RG [15,17] and which is linked to a leading order CFT approach [60] which was considered recently [18,19,61]. All our results can be extracted making use of the flow of the dimensionless renormalized potential $v(\varphi) = \mu^{-d} V(\mu^{d/2-1} Z \cdot \varphi)$, which includes the RG scale $\mu$ as well as a wavefunction renormalization matrix $Z_{ij}$ leading to a matrix of anomalous dimensions $\gamma = -\mu \partial_\mu \log Z$. For illustrative purpose we display the one loop flow

$$
\beta_\varphi = -d v + \frac{d - 2}{2} v_i \varphi_i + v_i \gamma_{ij} \varphi_i - \frac{1}{2} v_{ij} v_{jk} v_{kl} ,
$$

in which labels on $v(\varphi)$ correspond to derivatives with respect to the components $\varphi$ and repeated indices are summed over. As said it can be obtained both with RG and CFT methods and some general analysis can be found in [16,62]. An advantage of the approach is that all possible quantities related to the scaling of relevant and marginal spinless operators can be derived from the above equation. For the beta function of the coupling $\lambda$ as in [3], it is sufficient to insert the explicit form of the potential in (17) and simplify the result using the definitions of the hypertetrahedron vertices (2) and Eq. (1).

Composite and relevant operators, such as those of the previous sections, are similarly renormalized by deforming and linearizing the flow $v(\varphi) \to v(\varphi) + \mathcal{O}(\varphi)$, where $\mathcal{O}(\varphi)$ is the operator in question. In practice, we have that $\mathcal{O}(\varphi)$ is spinless and, therefore, we have to turn on each operator belonging to the irreducible representations by introducing an opportune source

$$
\mathcal{O}(\varphi) = \sum_{X=S,V,T,Z} J_X \cdot X(\varphi) ,
$$

which can be done for both quadratic and cubic deformations. The renormalization of the sources $J_X$ is multiplicative and easily leads to the corresponding critical exponents $\theta_X$ as a function of the couplings.

At the critical point the anomalous dimension matrix is diagonalized to $\gamma_{ij} = \frac{2}{3} \delta_{ij}$ defining the anomalous dimension, while the fixed point coupling $\lambda^*$ admits an expansion in $\sqrt{\epsilon}$ coming from the solution of its beta function. The expression of the critical coupling is used inside all RG function to determine the critical exponents in the $\epsilon$-expansion.

We denote with $\theta_X^{(n)}$ the critical exponent associated with the relevant deformation containing $n$ fields and irreducible multiplet $X = S,V,T,Z$ (which is enough up to $n = 3$). Starting with the bilinear operators, we find in the $\epsilon$-expansion (for results at second order see [59])

$$
\theta_S^{(2)} = 2 - \frac{5(q - 2)\epsilon}{3(3q - 10)} - \frac{(q - 2) (43 q^2 - 290 q + 900) \epsilon^2}{54 (3q - 10)^3} + \epsilon^3 \left\{ \frac{4(q - 2) (2q^3 - 3q^2 + 32q - 120)}{3(3q - 10)^4} \right\} ,
$$

\[3\] Here and in the following, “spinless” refers to field’s space (internal) indices and not spacetime’s and it means that the operator does not have uncontracted field indices.
\[ \theta_V^{(2)} = 2 - \frac{(5q - 16)\epsilon}{3(3q - 10)} - \frac{(q - 2) (43q^2 - 257q + 420) \epsilon^2}{54(3q - 10)^3} + \epsilon^3 \left\{ \frac{8(q - 3)(q - 2) (q^2 - 6q + 13) \zeta_3}{3(3q - 10)^4} \right\} 
- \frac{(q - 2) (8375q^4 - 101525q^3 + 464504q^2 - 958836q + 774720)}{1944(3q - 10)^5} \right\} \] (20)

\[ \theta_T^{(2)} = 2 + \frac{(q + 4)\epsilon}{3(3q - 10)} + \frac{(q - 2) (86q^2 + 101q - 840) \epsilon^2}{54(3q - 10)^3} + \epsilon^3 \left\{ - \frac{4(q - 2) (4q^3 - 3q^2 - 74q + 162) \zeta_3}{3(3q - 10)^4} \right\} 
+ \frac{(q - 2) (16750q^4 - 67603q^3 - 233960q^2 + 1384884q - 1432080)}{1944(3q - 10)^5} \right\} \] (21)

The critical exponent \( \theta_S^{(2)} \) is related to the scaling of the correlation length by \( \nu = 1/\theta_S^{(2)} \). Following the discussion of the previous sections, the exponents \( \theta_V^{(2)} \) and \( \theta_T^{(2)} \) have the meaning of fractal dimension of the clusters \( d_f = \theta_V^{(2)} \), and of the conductivity which we denote \( d_s = \theta_T^{(2)} \). We verify in general the scaling relation \( \theta_V^{(2)} = (d - 2 + \eta)/2 \) by Wallace and Young [25], which implies \( d_f = (d - 2 + \eta)/2 \). For completeness we give the anomalous dimension too

\[ \eta = - \frac{(q - 2)\epsilon}{3(3q - 10)} - \frac{(q - 2) (43q^2 - 257q + 420) \epsilon^2}{27(3q - 10)^3} + \epsilon^3 \left\{ \frac{16(q - 3)(q - 2) (q^2 - 6q + 13) \zeta_3}{3(3q - 10)^4} \right\} 
- \frac{(q - 2) (8375q^4 - 101525q^3 + 464504q^2 - 958836q + 774720)}{972(3q - 10)^5} \right\} \] (22)

The conductivity fractal dimension is most interesting for clusters with a simple geometric interpretation, which are \( q = 1 \) (percolations) and \( q = 0 \) (spanning trees and forest). In these limits we find

\[ d_{r,s.t.} = 2 - \frac{2\epsilon}{15} - \frac{7\epsilon^2}{225} + \left( \frac{27\zeta_3}{625} - \frac{221}{15000} \right) \epsilon^3, \] (23)
\[ d_{r,perc.} = 2 - \frac{5\epsilon}{21} - \frac{653\epsilon^2}{18522} + \left( \frac{356\zeta_3}{7203} - \frac{332009}{32672808} \right) \epsilon^3. \]

The crossover exponents are defined as \( \Phi = \nu \theta_V^{(2)} \) and \( \Phi = \nu \theta_T^{(2)} \), so that they govern the scaling close to criticality of non-symmetric deformations. We find

\[ \Phi = 1 + \frac{\epsilon}{3q - 10} + \frac{(q - 2)(79q - 140)\epsilon^2}{36(3q - 10)^3} + \epsilon^3 \left\{ \frac{-2(q - 2)(5q^2 - 10q - 14)\zeta_3}{(3q - 10)^4} \right\} 
+ \frac{(q - 2)(11903q^3 - 110840q^2 + 322172q - 242640)}{1296(3q - 10)^5} \right\} \] (24)

\[ \Phi = 1 + \frac{(q - 1)\epsilon}{3q - 10} + \frac{(q - 2)(q - 1)(133q - 320)\epsilon^2}{36(3q - 10)^3} + \epsilon^3 \left\{ \frac{-4(q - 2)(q - 1)q^2 - 7)\zeta_3}{(3q - 10)^4} \right\} 
+ \frac{(q - 2)(q - 1)(21893q^3 - 152996q^2 + 287972q - 30240)}{1296(3q - 10)^5} \right\} \] (25)

The first crossover exponent is constrained by the usual scaling relation to be equal to the thermodynamical exponent \( \beta = \nu(d - 2 + \eta)/2 = \Phi \). The second exponent is instead trivial for the percolations \( q \to 1 \), becoming \( \Phi = 1 \): this limit we verify at any order in the expansion, but can also be shown in general.
The critical exponents of deformations with three copies of the fields are

\[
\theta^{(3)}_S = \epsilon - \frac{(125q^2 - 794q + 1340)\epsilon^2}{18(3q - 10)^2} + \epsilon^3 \left\{ \frac{4(5q^3 - 44q^2 + 158q - 212)}{(3q - 10)^3} \right\}
\]

\[
\theta^{(3)}_T = -\frac{(q + 20)\epsilon}{3(3q - 10)} - \frac{(6q^3 - 627q^2 + 8250q - 21800)\epsilon^2}{54(3q - 10)^3}
\]

\[
\theta^{(3)}_Z = -\frac{2q}{3q - 10} - \frac{q(43q^2 + 272q - 1220)\epsilon^2}{18(3q - 10)^3} + \epsilon^3 \left\{ \frac{4q(2q^3 + 11q^2 - 142q + 288)}{(3q - 10)^4} \right\}
\]

All complete beta functions and critical exponents are provided through an ancillary file.

We do not give \(\theta^{(3)}_S\) and \(\theta^{(3)}_T\) for arbitrary \(q\) because for the vector subsector, which requires the diagonalization of a two-dimensional subspace, the final result is given by expressions very involved due to radicals. Instead, we give them only for the first few interesting values \(q = 0, 1, 2, 3\). For spanning forests

\[
\theta^{(3)}_V | q = 0 = \frac{17\epsilon}{15} - \frac{206\epsilon^2}{225} + \left( \frac{633\zeta_3}{625} + \frac{377527}{405000} \right) \epsilon^3,
\]

\[
\theta^{(3)}_V | q = 0 = 0,
\]

for percolations

\[
\theta^{(3)}_V | q = 1 = \frac{25 \pm \sqrt{889}}{42} \epsilon - \frac{2664841 \pm 92599\sqrt{889}}{4704588} \epsilon^2
\]

\[
\frac{50(4699 \pm 165\sqrt{889}) \zeta_3}{304927}
\]

\[
+ \frac{11(21667198601 \pm 725975407\sqrt{889})}{351319813488} \epsilon^3,
\]

\[
\theta^{(3)}_V | q = 2 = \frac{11\epsilon}{6} - \frac{445\epsilon^2}{216} + \left( \frac{35\zeta_3}{8} + \frac{53375}{15552} \right) \epsilon^3,
\]

\[
\theta^{(3)}_V | q = 2 = -\frac{\epsilon}{2},
\]

and finally for \(q = 3\)

\[
\theta^{(3)}_V | q = 3 = 6\epsilon - \frac{17\epsilon^2}{6} + \left( \frac{180\zeta_3 + 1713}{8} \right) \epsilon^3,
\]

\[
\theta^{(3)}_V | q = 3 = -\frac{11\epsilon}{3} - \frac{158\epsilon^2}{9} - \left( 16\zeta_3 + \frac{17380}{81} \right) \epsilon^3.
\]

There are several predictable patterns of degeneracy that we can check as a function of \(q\). A simple explanation goes as follows: because of their quantum numbers, the \(n\)-tensor operators are interpreted as generators of \(n\)-cluster functions, but, e.g. if \(n > q\), there are not enough states to label all different clusters, implying that the \(n\)-cluster operator must degenerate with some lower cluster. The pattern of degeneracies has been carefully explained in [21–23], here we just summarize our explicit findings based on those expectations.

- For \(q = 1\), corresponding to the universality class of percolations, the energy and 2-cluster operators degenerate, which implies a relation for the leading and subleading scaling exponents \(\theta^{(3)}_S | q = 1 = \theta^{(2)}_T | q = 1\) with \(M = 2, 3\). This is a well-known relation that has implications for the logarithmic behavior of percolations and allows to construct a logarithmic observable.

- For \(q = 2\), corresponding to the Ising universality class, the subleading energy and 3-cluster operators degenerate, but also the subleading magnetization and the 2-cluster operators degenerate. We have therefore \(\theta^{(3)}_S | q = 2 = \theta^{(3)}_Z | q = 2\) and \(\theta^{(2)}_V | q = 2\) with \(M = 2, 3\). However, upon inspection these relations become rather trivial because this is the Ising universality class in \(d = 6\) is above its upper critical dimension and therefore here has mean-field critical exponents.

- For \(q = 3\), the 3-states Potts mode, the twice-subleading magnetization and the 3-cluster degenerate, giving \(\theta^{(3)}_V | q = 3 = \theta^{(3)}_Z | q = 3\).

- For \(q = 4\) the subleading 2-cluster and the 3-cluster degenerate, giving \(\theta^{(3)}_T | q = 4 = \theta^{(3)}_Z | q = 4\).

An illustration of the degeneracies of the quadratic sector is given in Fig. 2. Many more degeneracies can be expected by going beyond in the spectrum of irrelevant operators, but the above summarize all the ones that we can verify with our computation and \(q \geq 1\). Degeneracies
for the spanning tree and forest model at $q = 0$ are more
delicate to observe. It has been argued that in this limit
the identity operator (and consequently its subleading
contributions, which coincide with the energy) degenerate
with the magnetization upon careful normalization of the
factors of powers of $q$ in the limit. It is arguably difficult
to observe the degeneracy of identity and magnetization
in the perturbative framework outside $d = 2$, since it
would go across energy levels by literally following the
discussion of [21]. We notice however that $\theta_{q}^{(3)}|_{q=0} = 0$
which agrees with $\theta_{V}^{(3)}|_{q=0} = 0$, instead of the expected
$\theta_{V}^{(3)}|_{q=0} \neq 0$.

\begin{align*}
\alpha_{X}^{(M)} &= \frac{\Delta_{X}^{(M)} - \Delta_{X}^{(M)}}{q - q_{c}} \bigg|_{q=q_{c}} = \theta_{X}^{(M)} - \theta_{X}^{(M)} \bigg|_{q=q_{c}} \quad (33)
\end{align*}

in which $X$ and $\bar{X}$ are the spins of the two degenerate
operators and $M$ is the order, as before. Above we have
also used the relation $\Delta_{X}^{(M)} = d - \theta_{X}^{(M)}$ to determine
the operator's scaling dimension, which strictly coincides
with the CFT scaling dimension only for non-descendant
operators. We have for percolations, $q = 1$, that $X = S$
and $\bar{X} = T$, resulting in

\begin{align*}
\alpha_{S}^{(2)} &= -\frac{2\epsilon}{7} + \frac{23\epsilon^{2}}{6174} + \left( \frac{48\zeta_{3}}{2401} + \frac{220751}{10890936} \right) \epsilon^{3}, \quad (34)
\alpha_{S}^{(3)} &= \frac{10\epsilon}{21} - \frac{3403\epsilon^{2}}{6174} + \left( \frac{1788\zeta_{3}}{2401} + \frac{32672808}{32672808} \right) \epsilon^{3}.
\end{align*}

Few other simple, but arguably less interesting, logarithmic
coefficients can be derived from our expressions
in the case of 3- and 4-states Potts model. For $q = 3$, we
have $X = V$ and $\bar{X} = Z$, resulting in

\begin{align*}
\alpha_{V}^{(3)} &= \frac{5\epsilon}{6} - \frac{283\epsilon^{2}}{72} - \frac{193483\epsilon^{3}}{7776}. 
\end{align*}

\section{VII. IN DEPTH EXAMPLE: $q = 4$}

It is interesting to examine more a special finite value of $q$, for which no analytic continuation is necessary, to illustrate in practice several features of the spectrum of quadratic deformations that we observed in the computations of the previous sections by comparing them with known literature's result. For this purpose, we choose the case $q = 4$, because it can be discussed in some detail, although we have conducted similar extensive checks for all the values $5 \leq q \leq 9$. For the comparison, we take appendix A of Ref. [62], in which the 4-states Potts field theory was discussed as a special case of a theory with general cubic interaction $\lambda_{ijk} \varphi_{i} \varphi_{j} \varphi_{k}$ without assuming $S_{4}$ symmetry a priori, but rather using only covariance of
the potential under the maximal symmetry group $O(3)$.

The obvious advantage of discussing the most general in-
teraction is that deformations of the potential are not
restricted by the symmetry group of the potential itself,
so we can observe how they arrange into $S_{4}$ multiplets.

The most general (symmetric) quadratic deformations
$\varphi_{i} \varphi_{j}$ includes six distinct combinations, $\varphi_{1}^{2}, \varphi_{2}^{2}, \varphi_{3}^{2}, \varphi_{1} \varphi_{2}, \varphi_{1} \varphi_{3}$ and $\varphi_{2} \varphi_{3}$, that have three distinct critical
exponents, denoted $\theta^{(2)}$ in [62], as relevant deformations
of the 4-states Potts model at criticality. These correspond

\begin{align*}
\alpha_{S}^{(2)} &= -\frac{2\epsilon}{7} + \frac{23\epsilon^{2}}{6174} + \left( \frac{48\zeta_{3}}{2401} + \frac{220751}{10890936} \right) \epsilon^{3}, \quad (34)
\alpha_{S}^{(3)} &= \frac{10\epsilon}{21} - \frac{3403\epsilon^{2}}{6174} + \left( \frac{1788\zeta_{3}}{2401} + \frac{32672808}{32672808} \right) \epsilon^{3}.
\end{align*}

For $q = 4$, we have $X = T$ and $\bar{X} = Z$, resulting in

\begin{align*}
\alpha_{V}^{(3)} &= \frac{5\epsilon}{6} - \frac{283\epsilon^{2}}{72} - \frac{193483\epsilon^{3}}{7776}. 
\end{align*}

\section{VII. IN DEPTH EXAMPLE: $q = 4$}

It is interesting to examine more a special finite value of $q$, for which no analytic continuation is necessary, to illustrate in practice several features of the spectrum of quadratic deformations that we observed in the computations of the previous sections by comparing them with known literature’s result. For this purpose, we choose the case $q = 4$, because it can be discussed in some detail, although we have conducted similar extensive checks for all the values $5 \leq q \leq 9$. For the comparison, we take appendix A of Ref. [62], in which the 4-states Potts field theory was discussed as a special case of a theory with general cubic interaction $\lambda_{ijk} \varphi_{i} \varphi_{j} \varphi_{k}$ without assuming $S_{4}$ symmetry a priori, but rather using only covariance of
the potential under the maximal symmetry group $O(3)$.

The obvious advantage of discussing the most general in-
teraction is that deformations of the potential are not
restricted by the symmetry group of the potential itself,
so we can observe how they arrange into $S_{4}$ multiplets.

The most general (symmetric) quadratic deformations
$\varphi_{i} \varphi_{j}$ includes six distinct combinations, $\varphi_{1}^{2}, \varphi_{2}^{2}, \varphi_{3}^{2}, \varphi_{1} \varphi_{2}, \varphi_{1} \varphi_{3}$ and $\varphi_{2} \varphi_{3}$, that have three distinct critical
exponents, denoted $\theta^{(2)}$ in [62], as relevant deformations
of the 4-states Potts model at criticality. These correspond

\begin{align*}
\alpha_{S}^{(2)} &= -\frac{2\epsilon}{7} + \frac{23\epsilon^{2}}{6174} + \left( \frac{48\zeta_{3}}{2401} + \frac{220751}{10890936} \right) \epsilon^{3}, \quad (34)
\alpha_{S}^{(3)} &= \frac{10\epsilon}{21} - \frac{3403\epsilon^{2}}{6174} + \left( \frac{1788\zeta_{3}}{2401} + \frac{32672808}{32672808} \right) \epsilon^{3}.
\end{align*}

For $q = 4$, we have $X = T$ and $\bar{X} = Z$, resulting in

\begin{align*}
\alpha_{V}^{(3)} &= \frac{5\epsilon}{6} - \frac{283\epsilon^{2}}{72} - \frac{193483\epsilon^{3}}{7776}. 
\end{align*}
to the operators \( S^{(2)}, V^{(2)} \) and \( T^{(2)} \) of Sect. III, which appear with the correct multiplicities of the \( S_q \) irreducible representations, as can be evinced by substituting \( q = 4 \) in Eqs. (19), (20) and (21). Notice that the vector has multiplicity three because it has three independent components, while the tensor has multiplicity two.

The situation becomes more complicate when discussing the symmetric cubic deformations \( \varphi_i\varphi_j\varphi_k \) denoted \( \theta^{(3)} \). There are a total of ten distinct combinations that have four distinct critical exponents in Ref. [62]. Direct inspection reveals that one exponent correspond to the singlet \( S^{(3)} \), and two are conjugate exponents corresponding to the mixing vectors \( V^{(3)} \) and \( V^{(3)}' \). The remaining deformations arrange in a multiple of three components that share the same critical exponent \( \theta^{(3)} \sim O(\epsilon^2) \). In this case one can notice the degeneracy \( \theta_T^{(3)} = \theta_Z^{(3)} \) for \( q = 4 \), as one can check from Eqs. (27) and (28), but keeping in mind that in this case the \( Z \) sector is not really physical by itself since it would be characterized by a negative dimensional space (see Eq. (8)), just opposite to the \( T \) sector. This is of course the reason why the \( T^{(3)} \) and \( Z^{(3)} \) operators combine in the analytic continuation to \( q \rightarrow 4 \) resulting in a Jordan pair and a corresponding log-CFT. Since in this paper we arranged deformations according to the irreducible representations of \( S_q = S_{N+1} \), while in [62] we arranged them according to the irreducible representations of \( O(N) \), we deduce that the additional vector does not transform according to any representation of \( S_q \subset O(N) \), but rather carries a representation label of \( O(N) \). This can be checked explicitly by looking at the components of the deformation.

The interesting aspect of the above discussion is that the deformation that does not carry a label of the symmetry group \( S_q \) of the critical point has critical exponent with expansion starting at \( O(\epsilon^2) \), in other words at the NLO of the \( \epsilon \)-expansion. We conjecture here that this might be a general feature, namely that if a deformation of a critical point carries no irreducible representation label of the symmetry of the critical point itself, such deformation has a critical exponent with expansion that starts at least at \( O(\epsilon^2) \). It would be interesting to test these features using a non-perturbative approach to the RG such as [11], which allows to work directly in a physically interesting dimension, such as \( d = 2 \) or \( d = 3 \).

Finally, the analysis presented in [21] and verified in this paper suggests that for \( q = 4 \) the operators \( T^{(3)} \) and \( Z^{(3)} \) take pair of the same Jordan cell and for a logarithmic pair. In fact, for \( q = 4 \) they do not have enough components to form actual tensors and their scaling dimensions do not show in the analysis of [62]. In order to see them, it would be necessary to construct opportune observables as done for the case \( q = 1 \) in Ref. [22, 24].

VIII. RG ESTIMATES FROM \( d = 4 - \epsilon \)

In \( d = 4 - \epsilon \) there are several universality classes of field theories with multiple scalar fields. The discussion of these models is both old [63–66] and new [16, 67], and their general classification is still incomplete [67, 68].

The hypertetrahedral model in \( d = 4 - \epsilon \) dimensions has received considerably less attention over the years, both among its peers and compared to the sibling in \( d = 6 - \epsilon \). The study of the renormalization group flow of the couplings \((u, v)\) reveals three nontrivial fixed points. Two are not of interest for us, because they do not have \( S_q \) symmetry: one is the well-known \( O(N) \)-symmetric fixed point of Wilson-Fischer, and the other one that represents \( N \) decoupled \( \phi^4 \) models, although in a parametrization that does not make it straightforward to see and might require inspection of the spectrum. In both cases, the number of fields is \( N = q - 1 \). This situation is very reminiscent of what is found when looking at the analog system for the hypercubic model [69, 70].

The last fixed point is the one with genuine \( S_q \) symmetry, which is thus named hypertetrahedral.

We computed all the same quantities for the hypertetrahedral model that we computed in the previous section, starting from the RG in \( d = 4 - \epsilon \) at next-to-next-to-leading order. For illustrative purposes, we display it here at the leading order

\[
\beta_u = d v + \frac{d - 2}{2} v_i \varphi_i + v_i \gamma_{ij} \varphi_i + \frac{1}{2} v_{ij} v_{ij},
\]

\[
\gamma_{ij} = \frac{1}{12} v_{ijkl} v_{jklm},
\]

for which summation over repeated indices is assumed.

We want to report briefly some of such quantities, because, to the best of our knowledge, most of them have not been given elsewhere. We still denote with \( \theta_X^{(n)} \) the critical exponent associated with the relevant deformation containing \( n \) fields and irreducible multiplet \( X = S, V, T, Z \), which should not be confused with those given in the case of the Landau-Potts field theory. We find for the \( n = 2 \) sector

\[
\theta_S^{(2)} = 2 - \frac{2q\epsilon}{3(q + 2)} + \frac{q (19q^3 - 258q^2 + 1332q + 648) \epsilon^2}{162(q - 6)(q + 2)^3} + \epsilon^3 \left\{ -\frac{4q (q^3 - 3q^2 - 20q^2 + 228q + 144) \zeta_3}{27(q - 6)(q + 2)^4} + \frac{q (937q^7 + 28770q^6 - 463356q^5 + 2772360q^4 - 8850384q^3 + 11018592q^2 + 9471168q + 6998400)}{17496(q - 6)^3(q + 2)^5} \right\},
\]

(38)
\[ \theta_{V}^{(2)} = 2 - \frac{q \epsilon}{3(q+2)} + \frac{q}{162(q-6)(q+2)^3} \left( -19q^3 - 132q^2 + 828q + 432 \right) \epsilon^2 + \epsilon^3 \left\{ \frac{4q \left( q^4 + 6q^3 - 5q^2 - 150q - 72 \right) \zeta_3}{27(q-6)(q+2)^4} ight. \\
\left. + \frac{q}{17496(q-6)^3(q+2)^5} \left( -937q^7 + 9666q^6 - 77220q^5 + 974808q^4 - 5519664q^3 + 7488288q^2 + 8071488q + 5318784 \right) \right\}, \]  

\[ \theta_{F}^{(2)} = 2 + \frac{2 \epsilon}{3(q+2)} + \left\{ \frac{-3q^4 + 124q^3 - 252q^2 + 1008q + 864}{162(q-6)(q+2)^3} \right\} \epsilon^2 - \epsilon^3 \left\{ \frac{8 \left( q^4 + 6q^3 - 7q^2 + 102q + 72 \right) \zeta_3}{27(q-6)(q+2)^4} ight. \\
\left. + \frac{-327q^6 + 4354q^5 + 93972q^4 - 1099512q^3 + 4173552q^2 - 6192288q^3 + 5800896q^2 + 11477376q + 6718464}{17496(q-6)^3(q+2)^5} \right\}. \]  

As before we include the anomalous dimension for completeness

\[ \eta = \frac{q(q+6)\epsilon^2}{54(q+2)^2} + \frac{q(109q^3 + 642q^2 + 3852q + 2808) \epsilon^3}{5832(q+2)^4} . \] 

Some degeneracies of the quadratic sector are displayed in Fig. 3.

Notice that the plot highlights a further degeneracy, involving the scalar and vector quadratic deformations, that is both interesting and trivial. It is interesting because the scalar and vector deformations are to be degenerate, which is arguably not easy to see in the \( \epsilon \)-expansion. However, the result is trivial, in the sense that it is mean-field, because

\[ 2 = \theta_{S}^{(2)} = \theta_{V}^{(2)} \text{ for } \epsilon \to 0. \]  

Nevertheless, the universal coefficient of the logarithm associated to this degeneracy is non trivial and given by \( (X = S \text{ and } X = V \text{ in Eq. (33)}) \)

\[ \alpha_{S}^{(2)} = \frac{\epsilon}{6} + \frac{\epsilon^2}{36} - \left( \frac{\zeta_3}{9} - \frac{1}{72} \right) \epsilon^4. \] 

Even though this degeneracy was expected on the basis of the continuation to \( \epsilon \to 0 \) of the representation theory of \( S_q \) (see the relevant discussion appearing in [21]), we did not observe it in Sect. VI, so it is amusing to see it here. In fact, this is the only logarithmic coefficient that we display for the reduced Landau-Potts model, especially because it might be relevant for applications to the random cluster model [18]. We stress, however, that analog universal coefficients for the other two degeneracies (the same that are shown in Fig. 3) can be obtained in a similar way.

The expressions are easy to specialize to obtain the fractal dimensions as before. We could still refer to the limits \( q \to 0 \) and \( q \to 1 \) as spanning forest and percolation, respectively, however, to our knowledge, the potential relations of these limits with the mentioned models has not been explored in the case of the hypertetrahedral model. In the limit \( q \to 0 \) we have

\[ d_{r,q=0} = 2 - \frac{\epsilon}{3} - \frac{\epsilon^2}{9} + \left( \frac{2\zeta_3}{9} - \frac{1}{18} \right) \epsilon^3, \]

\[ d_{f,q=0} = 2, \] 

while in the limit \( q \to 1 \)

\[ d_{r,q=1} = 2 - \frac{2 \epsilon}{q} - \frac{1741 \epsilon^2}{21870} + \left( \frac{280 \zeta_3}{2187} - \frac{20976487}{531441000} \right) \epsilon^3, \]

\[ d_{f,q=1} = 2 - \frac{\epsilon}{q} - \frac{1109 \epsilon^2}{21870} + \left( \frac{176 \zeta_3}{2187} - \frac{16262513}{531441000} \right) \epsilon^3. \] 

The crossover exponents are defined as before as the ratio of critical exponents. For the case \( n = 2 \) we find

\[ \Phi = 1 + \frac{q \epsilon}{6(q+2)} - \frac{q \left( 10q^3 - 27q^2 + 360q + 108 \right) \epsilon^2}{162(q-6)(q+2)^3} + \epsilon^3 \left\{ \frac{2q \left( q^4 + 3q^3 - 25q^2 + 78q + 72 \right) \zeta_3}{27(q-6)(q+2)^4} ight. \\
\left. - \frac{q \left( 734q^7 + 1149q^6 - 64404q^5 + 3288660q^4 - 850176q^3 + 1839024q^2 + 699840q + 419904 \right)}{8748(q-6)^3(q+2)^5} \right\}, \]  

\[ \Phi = 1 + \left( \frac{q-1}{3(q+2)} \right) \left( \frac{7q^3 + 143q^2 - 78q - 72}{162(q+2)^3} \right) \epsilon^2 + \epsilon^3 \left\{ \frac{2(3q^4 - 3q^3 - 38q^2 + 14q + 24) \zeta_3}{27(q+2)^4} ight. \\
\left. - \frac{361q^7 + 3509q^6 - 43470q^5 + 333792q^4 - 1070496q^3 + 99792q^2 + 396576q + 279936}{8748(q-6)^3(q+2)^5} \right\}. \] 

We derived similar unwieldy expressions for all the cubic operators, which we refrain from giving here because of...
space. All complete beta functions and critical exponents are provided through an ancillary file.

We have also explicitly checked that all expected patterns of degeneracy in the spectrum are still present. The reason is that, following the logic of Refs. [21, 22], these degeneracies are related to the symmetry of the model, and are thus shared between the Landau-Potts and hypertetrahedral field theories. This suggest the possibility of constructing several more log-CFTs as limits in $d = 4 - \epsilon$ dimensions. In this respect, the computation of the universal coefficients of the logarithms follows exactly the same steps as before.

The analysis of the critical point of the $q$-states Potts model can be done using the standard Landau-Ginzburg approach, which we have applied to three loop order to obtain next-to-next-to-leading order exponents in the $\epsilon$-expansion. While $\epsilon$-expansion converges rather poorly for interesting values of lower dimensions of interest such as two or three, it is still a very convenient tool when it comes to unveiling universal properties. One such property is the dependence on the parameter $q$ of critical exponents. We have computed the exponents associated to non-singlet deformations of the Landau-Ginzburg potential of second and third order in the field.

In short, our work adds the next-to-next-to-leading order in the computations of non-singlet deformations of the Landau-Potts field theory with $\phi^4$-type interaction, discusses the same order for the restricted Potts field theory with $\phi^4$-type interaction (also known as the restricted Potts model), and combines all the results to provide estimates of crossover exponents, fractal dimensions of propagator lines and new universal quantities related to logarithmic CFTs.

Non-singlet deformations are interesting because they are related to statistically and geometrically meaningful observables, thus allowing to estimate the corresponding critical exponents. In particular, we have estimated critical crossover exponents for the breaking of the $S_q$ symmetry when the temperature is at its critical value. In a similar fashion, we have computed the expansion of the fractal dimensions associated to Potts clusters. Finally, we used the full power of the $q$-dependence of our estimates to discuss the emergence of logarithmically scaling operators in the underlying CFT. The discussions on logarithms is particularly interesting because it shows that there are new universal quantities, the coefficients of such logarithms, that can be computed by means of RG methods and that require a complete handle on the $q$-dependence of the spectrum.

On this note, having accepted the limitations of the $\epsilon$-expansion in this particular context, one important point that our paper shows is that several interesting quantities, CFT's logarithms among all, are accessible within RG techniques. This implies that they could be computed by RG methods other than dimensional regularization to improve the value of the corresponding estimates. This is an interesting possibility in the light that recent works have shown that the logarithmic effects are visible when studying the scaling of relatively simple observables [22, 24].

Acknowledgments The work presented in this paper was inspired by a relatively recent paper by Kompaniets and Wiese, which studied similar quantities for the $O(N)$ model [31]. For performing the computations, we relied heavily on the Mathematica packages [21] and [74]. OZ is grateful to R. Ben Ali Zinati for several discussions on the topics covered by this work.
