(Dated: December 21, 2013)

A “bucket brigade” architecture for a quantum random memory of \( N = 2^n \) memory cells needs \( n(n+5)/2 \) times of quantum manipulation on control circuit nodes per memory call. Here we propose a scheme, in which only average \( n/2 \) times manipulation is required to accomplish a memory call. This scheme may significantly decrease the time spent on a memory call and the average overall error rate per memory call. A physical implementation scheme for storing an arbitrary state in a selected memory cell followed by reading it out is discussed.

Keywords: quantum random memory, bucket brigade, microtoroidal resonator

A random access memory (RAM) is a fundamental computing device, in which information (bit) can be stored in any memory cell and be read out at discretion [1,2]. A RAM is made up of an input address register, a data register, an array of memory cells, and a controlling circuit. A unique address is ascribed to each memory cell, the address register is dispatched through the circuit, followed by reading it out. A general RAM is a RAM working in a way quantum Fourier transform, and quantum searching on a classical database [3]. A general QRAM is an indispensable for the performance of many algorithms, such as quantum searching [10], element distinctness [11,12], collision finding [13], general NAND-tree evaluation [14], and signal routing [15].

In a seminal paper [13,16], Giovannetti et al. (GLM) proposed a promising bucket-brigade architecture for QRAMs, which exponentially reduce the requirements for a memory call. However, in GLM scheme, \( n \) times of quantum unitary transformations per memory call is required to turn one quantum trit initialized in \(|\text{wait}\rangle\) in each node of the control circuit into \(|\text{left}\rangle\) or \(|\text{right}\rangle\), and all flying qubits including address qubit and bus qubit can pass through an arbitrary node of the controlling circuit only if a successful quantum manipulation has been performed on the trits, leading to the times of manipulations on the nodes \( N_c = n(n+5)/2 \) per memory call for \( 2^n \) memory cells, where \( n \) is the number of bits in the address register. Here we present a QRAM scheme, where the quantum object in every node have only two possible states \(|\text{left}\rangle\) and \(|\text{right}\rangle\). On average the times of quantum manipulations on the nodes per memory call can be reduced to \( N_c = n/2 \), significantly decreasing both the decoherence rate and the time spent on a QRAM call. A physical implementation for information storage and read-out on a QRAM is presented.

The main idea is shown in Fig1. The \( N \) memory cells are positioned at the end of a bifurcation control circuit with \( n = \log_2 N \) levels. At each node of the control circuit there is a qubit with two states \(|\text{left}\rangle\) and \(|\text{right}\rangle\). The state of the \( j \)th qubit in the address register controls which route to follow when a signal arrives at a node in the \( j \)th level of the circuit: if the node qubit is \(|0\rangle\), the left path is chosen; if it is \(|1\rangle\), the right path is chosen. For example, an address register \(|0\rangle\) means that left at the 0th level, left at the next, and right at the second. Illuminated by a control laser pulse a node qubit in state \(|\text{left}\rangle\) will flip to \(|\text{right}\rangle\) if the incoming address qubit is \(|1\rangle\), or remain in \(|\text{left}\rangle\) if the address qubit is \(|0\rangle\). Without the control pulse, a node qubit in \(|\text{left}\rangle\) \(|\text{right}\rangle\) will deviate any incoming signal along the left(right) side route.

First, all the node qubits are initialized in state \(|\text{left}\rangle\). Then the first qubit of the address register is dispatched through the circuit. At the first node, the address qubit incurs a unitary transformation \( U \) on the node qubit with the help of a control pulse \( \Omega(t) \): \( U|0\rangle|\text{left}\rangle = |0\rangle|\text{left}\rangle \) and \( U|1\rangle|\text{left}\rangle = |0\rangle|\text{right}\rangle \). Next the second qubit of the address register is dispatched through the circuit, follow left or right route relying on the state of the first node qubit, and arrives at one of the two nodes on the second level of the circuit. The node qubit illuminated by the control pulse will make a corresponding state change
Finally, all the node qubits are reset to single out a memory cell. After that an arbitrary uncontrolled manipulations are really performed in each memory call. After all the qubits of the address register have gone through the whole circuit, a unique path of n qubits has been singled out from the circuit (see Fig.1). Subsequently, a single photon is sent along the selected path to single out a memory cell. After that an arbitrary uncontrolled manipulations are really performed in each memory call. Therefore the average times of quantum manipulations per node qubit flip event is n/2, or will transmit the resonator and go along the right path if the atom is in |right⟩. When the second address qubit is sent out and meet the first node, it will be reflected back and travel along the left path by applying an optical circulator in one side of the tapered fiber (see Fig.2 b) if the atom in the first node is in |left⟩, or will transmit the resonator and go along the right path if the atom is in |right⟩. When the second address qubit arrive at one of the two nodes on the second level, it will be coherently stored in the node atom and left the atom in |left⟩ or |right⟩ dependent on the photon number contained in the address qubit, and so on.

We assume that each quantum memory cell in the memory array consists of a memory atom m and an ancillary atom a, which are confined in two harmonic traps and positioned inside a high quality cavity (see Fig.3). The ancillary atom has a three-level structure: \(|g⟩_a\) is coupled to \(|e⟩_a\) by the field of the cavity mode with strength \(g_a\); \(|s⟩_a\) is coupled to \(|e⟩_a\) by a classic control field \(Ω(t)\), where the subscript \(a\) denotes an ancillary atom. After a path to the memory array is singled out, a single-photon is sent along the path to the selected memory cell. A control laser pulse \(Ω(t)\) is applied to the ancillary atoms initialized in state \(|g⟩_a\) at the moment when

![FIG. 1. (color online). Schematics for a quantum random access memory. In each node of the binary control circuit, a qubit in |right⟩(|left⟩) routes the approaching signals right (left). A single photon can excite the qubit from |left⟩ to |right⟩ with the aid of a classical impedance-matched control field \(Ω(t)\). Here the third level memory cell |001⟩ is addressed through the selected path marked with red circles. The read-out state is transferred to a data register along the path marked with black squares.](image-url)
the photon arrives at the memory cell, resulting a state
flip of atom a to |s⟩a [20, 21]. To avoid to be involved
into the quantum operations aimed on the selected
memory cell, the ancillary atoms non-selected are excited to a
stable state |t⟩a by a π pulses on transition |g⟩a → |t⟩a.
Next we can do some quantum manipulations either to save
an arbitrary unknown quantum state in the selected
memory cell or to read out its content.

In the first place, we discuss how to save an arbitrary
unknown quantum state in the memory cell identified
by the address register. First, an initialization operation
on the memory cell array is performed. This can be
realized as follows: atom a in state |s⟩a is excited to a Rydberg state |r⟩a by two-photon stimulated Ra-
dberg (TWSR) pulses [22]. TWSR pulses on the transition
|s⟩m → |r⟩m (in terms of the perturbed state ) of the
memory atoms are applied, resulting the selected memory
atom being excited to |r⟩m and immediately flipping to the ground state |g⟩m through spontaneous radiation
(see Fig3B). In this way only the memory atom in the
selected memory cell is reset in state |g⟩m, leaving the
content of the others unchanged, because the states |r⟩m
of the non-selected memory atoms are off resonant with
the TWSR pulses due to the absence of the strong Ryd-
berg dipole interactions [23]. The ancillary atom in Ryd-
berg |r⟩a is brought to the ground state |g⟩a by applying a
π pulse on its transition |r⟩a → |g⟩a.

Second, an arbitrary unknown state α|0⟩p + β|1⟩p with Fock bases |n⟩p (n = 0, 1) is transferred along the selected
path to the memory cells. On the arrival of the signal a classic control pulse Ω(t) is applied on the ancillary
atoms initialized in the ground state |g⟩m, leading to a state map (α|0⟩p + β|1⟩p)|g⟩a → |0⟩pα|g⟩a + β|s⟩a) [20].

State α|g⟩a + β|s⟩a is then transferred to a memory
atom by employing the strong dipole interaction between
two Rydberg atoms [24, 25]. When both of the memory
atom and the ancillary atom are in Rydberg states, the
strong dipole interaction between them will couple their
motion, which is best described in the basis of normal
modes |j⟩m (j = 0, 1, 2, ...). All the motion modes of the
atoms are initially cooled to near their ground state by
Raman sideband cooling on them [26].

Third, we drive a π pulse on transition on |g⟩m → |r⟩m
on memory atoms to excite the memory atoms from
state |g⟩m to state |r⟩m. Fourth, a π pulse on transition
|g⟩a → |r⟩a|0⟩m and a blue sideband (BSB) pulse on transition |s⟩a → |r⟩a|1⟩n, are applied on the ancillary
atoms, leading to state

\[ |ψ⟩_1 = α|r⟩_a|r⟩_m|0⟩_n + β|r⟩_a|r⟩_m|1⟩_n \] (1)

for the selected memory cell (see Fig. 3B) and state

\[ |ψ⟩_2 = (α_x|r⟩_m + β_x|s⟩_m)|t⟩_a \] for other memory cells with their initial states α_x|g⟩_m + β_x|s⟩_m (see Fig. 3C).

Here we have used the fact that the normal mode of
motion is shared by the memory atom and the ancil-
lar atom, both of which are in Rydberg states. Fifth,
a π pulse on the transition |r⟩m → |g⟩m unperturbed by the
strong dipole interaction between two Rydberg atoms
is applied on the non-selected memory atoms to restore
them to their initial states α_x|r⟩_m + β_x|s⟩_m.

Sixth, a π pulse on transition |r⟩_m|1⟩_n → |r⟩_m|0⟩_n
illuminates the memory atoms, resulting a state mapping

\[ |ψ⟩_1 → |ψ⟩_2 = α|r⟩_a|r⟩_m|0⟩_n + β|r⟩_a|r⟩_m|1⟩_n. \] (2)

Seventh, two π pulses on |r⟩_m|0⟩_n → |s⟩_m and |r⟩_m|0⟩_n → |g⟩_m, respectively, are applied on the memory atom,
leading to an unitary transformation |ψ⟩_2 → |ψ⟩_3 =

\[ (α|g⟩_m + β|s⟩_m)|t⟩_a \; \text{where the unknown state } \alpha(0) + β(1) \text{ has been stored on the selected memory atom.} \]

Note that this two pulses will not affect the states of the non-selected memory atoms since the pulses is detuned from the transitions |r⟩_m → |s⟩_m and |r⟩_m → |g⟩_m, which are free of the influence of strong dipole interaction between two
Rydberg atoms. Eighth, the ancillary atoms is restored to
the ground state |g⟩_a by a π pulse on the transition

\[ |r⟩_a → |g⟩_a \] (see Fig3E), and the non-selected ancillary
atoms are restored to the ground state |g⟩ for the next
memory call by flipping to a intermediate level with a
pulse and then falling to |g⟩ through spontaneous radia-
tion. In this way an arbitrary unknown state can be transferred to the selected memory atom, leaving the
states of other memory atoms unchanged.

Now we discuss how to read out the content of the se-
lected memory atom α_x|g⟩_m + β_x|s⟩_m. First, a π pulse on transition |s⟩_a → |r⟩_a is employed to excite the
selected ancillary atom to state |r⟩_a. Second, we em-
ploy two π pulses on transition |g⟩_m → |r⟩_m|0⟩_n and

\[ |s⟩_m → |r⟩_m|1⟩_n, \]
respectively (see Fig3F), driving the system of the selected atoms m and a into state

\[ |ψ⟩_4 = α_x|r⟩_m|r⟩_a|0⟩_n + β_x|r⟩_m|r⟩_a|1⟩_n. \] (3)

Third, a π pulse on transition |r⟩_a|1⟩_n → |r⟩_a|0⟩_n
drive the selected system into state |r⟩_m(α_x|r⟩_a +

(A) An address qubit consisting of zero or one photon is split equally in counter-propagating directions and coherently stored using an impedance-matched control field \( \Omega(t) \), leading to a state flip of the atom conditioned on the photon number. (B) By employing an optical circulator an photon travels along a tapered fiber being in critical coupling to the resonator will go along the left (right) path if the atom is in state \( |left⟩(|right)⟩ \).](https://example.com/figure2.png)
FIG. 3. (color online). Schematics for writing to and reading out of a memory cell. (A) A single-photon can be coherently stored in a memory cell consisting of two atoms m and n positioned inside of a high-Q cavity with a time-dependent control pulse Ω(t). Diagrams of energy levels and pulses sequences for storing unknown state to the selected memory cell (B to E) and for reading out of the content of the selected memory cell (F to H).

βx|r⟩a|0⟩n (see Fig.3G). Fourth, the selected memory atom is sent to the ground state by a π pulse on the transition |r⟩m|0⟩n → |g⟩m. Fifth, two pulses on the transition |r⟩a → |g⟩a and |r⟩a → |s⟩a, respectively, set the selected ancillary atom in state αx|g⟩a + βx|s⟩a (see Fig.3H); the content of the select memory atom is transferred to the ancillary atom. Note that these pulses do not influence the non-selected atoms a and m because they have no strong dipole interaction. By applying a classical impedance-matched control field Ω(t), a matter-photon mapping ⟨αx|g⟩a + βx|s⟩a|0⟩p → |g⟩a(αx|0⟩p + βx|1⟩p) can be accomplished [20, 21], transferring the state of the selected memory cell to the flying qubit and leaving the ancillary atom in state |g⟩a. The flying qubit goes along the path with black squares to the data register (see Fig.3H). Finally, the non-selected ancillary atoms are initialized to state |0⟩a for a next task.

In summary, we have presented a scheme for a quantum random access memory. With three-level memory system been substituted by a qubit in every node of the control circuit, this structure may significantly reduce overall error rate per memory address and the memory address time. In addition, we have discussed a physical implementation based on microtoroidal resonator and strong-dipole interaction between two Rydberg atoms for a QRAM writing and read-out. The microtoroidal resonator and the tapered fiber may be replaced by a surface plasmon propagating on the surface of a nanowire-conductor-dielectric interface [27, 23].
