Abstract

Background

Above ground biomass (AGB) is a useful measure for assessing changes in forest structure and functional, and play a significant role in studying carbon stocks, the effect of deforestation and carbon sequestration on the global carbon balance. The present study aimed to study the relationship between AGB and community parameters in Sal forests of Eastern India through stratified random sampling by lying 92 belt transects each of 0.5 ha size.

Results

It recorded a high AGB (410.70 Mg ha⁻¹), and carbon stock (Cp) (193.06 Mg C ha⁻¹), and forest wise AGB ranged from 0.19 to 24.75 Mg ha⁻¹ (mean 4.45 ± 0.45 SE). The spatial pattern of AGB showed that maximum studied forests (65%) had very low AGB (<5.00 Mg ha⁻¹), and only one forests (1%) located in the northwest comer of Ranchi had very high AGB (>20 Mg ha⁻¹). Species wise AGB ranged from 0.001 to 7074.94 Mg ha⁻¹ (mean 106 ± 71 SE) and Shorea robusta with maximum basal area (120.81 m² ha⁻¹) contributed maximum AGB (64.87% of the total AGB), however, no similar trends have been observed in any other tree species. A significant positive correlation was observed between AGB and Cp (r=1.00, p<0.01), H’ (r= .58, p<0.01), Dmg (r= .31, p<0.01), Dmn (r= .49, p<0.01), ENS (r= .57, p<0.01), E (r= .26, p<0.05), and basal area (r= 0.71, p<0.05). However, a negative correlation of AGB was evident with CD (r= -.57, p<0.01), and density (r= - 0.17).

Conclusions

The relationships differed greatly among plant diversity attributes, basal area, density, AGB, and Cp within and among various forests and the strongest relationships within each forests were always those having greater richness (Dmg, Dmn), diversity (H, ENS), basal area or evenness (E). Estimation of forest Cp enables us to assess the amount of carbon loss during deforestation or the amount of carbon stored during forest regeneration. The present study will directly help in studying the response of climate change on ecosystem productivity, energy and nutrient flow, and for assessing the patterns of carbon sequestration in Indian forests under global climate change.

Background

Forests are considered as important terrestrial carbon reserves and pools (Whittaker and Likens, 1975) that greatly influence the lives of humans as well as other organisms. Forests act as natural carbon sinks, and play the most significant role by producing large carbon pools stored as vegetation biomass including storage of carbon in the soil (Brown and Lugo, 1992). The carbon acquired from the atmosphere is fixed through photosynthesis to form organic compounds (Alexandrov, 2007). Thus, atmospheric carbon becomes a part of the plant body and stored for a longer period of time in different plant parts. Forest biomass is an important source of food, fodder and fuel, and its exploitation leads to
Forest degradation (Rawat and Nautiyal, 1988). Forest biomass quantification has attracted renewed interests as it represents ca. 44% of the world forest carbon pool (Pan et al., 2011), thereby playing a key role in climate change mitigation. Above ground biomass (AGB) is a useful measure for assessing changes in forest structure and functional (Brown et al., 1999; Kumar et al., 2019) and play a significant role in studying carbon stocks, the effect of deforestation and carbon sequestration on the global carbon balance (Ketterings et al., 2001). AGB estimates are critical to analyze the carbon stocks and fluxes of forests (Brown et al., 1997; Návar, 2009) and also help in quantification of the structural attributes of forest ecosystems across a wide range of environmental conditions (Brown et al., 1999) as well as the amount of carbon lost from sinks through deforestation and degradation (Ketterings et al., 2001; Houghton, 2005). The biomass in tropical deciduous forest is not uniformly distributed and exhibits patchy distribution (Chaturvedi et al., 2011). Estimating the amount of forest biomass gives an idea of carbon sequestration potential of forests (Murthy et al., 2013). Absolute measurements of biomass can be taken up only at the time of felling which is not possible in all situations (Murali et al., 2005).

Measurements for GBH, height, and species-specific gravity in the field are good criteria for estimating biomass as nondestructive methods (de Gier, 2003). Therefore, carbon stock of trees can be estimated using an allometric/volumetric equation (Thapa-Magar and Shrestha, 2015). Tree diameter and height data used to estimate carbon stocks through the calculation of AGB by using species specific allometric/volumetric equations (Ketterings et al., 2001; Chave et al., 2005). Plant biomass has a direct relationship with the amount of carbon present in that plant biomass. Based on the results of different studies related to the estimation of carbon in wood, it was observed that carbon varied from 45% to 50% for different ecosystems and all biomass pools contained 47.5% carbon (Kotto-Same et al., 1997).

Ecosystem stability, and its resilience are dependent on plant diversity attributes, such as species richness, evenness, and composition (identity of species) (Tilman and Downing, 1994; Naeem et al., 2000). The impacts of land clearing due to proliferation of agriculture, urban sprawl, natural hazards (forest fires, insects, diseases, droughts, frosts), and exploitation activities (illegal forest clearance, etc.) on forests can only be understood by these plant diversity attributes (Dogan and Dogan, 2003). These visual tools enable us to understand the nature, and characteristics of land cover, and species distributions. Species diversity is the combination of species richness, and evenness, and it is the number of biological units present at a given location at a given time taking into account the distribution pattern of individuals amongst the species. The most commonly used measures of species diversity are the Shannon function, species richness, and evenness (the distribution of abundance among the species, also known as equitability) (Feroz et al., 2015). Species richness is a measure being more influenced by seedlings recruitment, whereas species evenness is influenced by species interactions like competition (Wilsey and Gray, 2007). The consideration of species richness without any other key attributes of species assemblages could be a misleading indicator of plant diversity in terms of conservation perspective (Stirling and Wilsey, 2001; Ma, 2005). On the other hand, species evenness has an important role in conservation of biological diversity (Mattingly et al., 2007) as with the changes in evenness, the distribution of functional traits of an ecosystem used to be affected (Chapin et al., 2000; Hillebrand et al., 2008). The shift in evenness used to be occurred much earlier than the species richness in any
community. Therefore, tracking species evenness can provide some kind of early warning regarding the disturbances going on in the community (Anonymous, 2015). The variation in both evenness and diversity is being regulated by richness (Hill, 1973), and evenness significantly determines the change in species diversity than richness (Mligo, 2018) as it holds a major contribution in the diversity (Triin et al., 2009). Thus, species evenness provides adequate information on change in plant diversity with comparatively higher gradients than richness (Mligo, 2018).

Tropical deciduous forests of India are species rich with irregular distribution of tree densities and basal covers as well as multistoried canopy structures with different microclimate makes it complex to understand the patterns of AGB over space and time within and among the different forests (Behera et al., 2012). Additionally, species diversity, richness, evenness, or dominance represent critical attributes of plant diversity that may have associations with AGB. A very limited study has examined the AGB-plant diversity attributes relationships in forests, perhaps because of the difficulty of using AGB as a substitute for productivity in long-lived trees (Vance-Chalcraft et al., 2010). However, describing the relationship between species richness and AGB in forests is useful beyond the context of forest productivity. Therefore, the present study aimed to assess spatial pattern of tree diversity, and AGB by using species specific volumetric equations in Sal forests of Ranchi, Jharkhand, Eastern India as well as estimation of carbon stock (Cp) based on the AGB results. An effort has also been made to examine the relationships between multiple attributes of plant diversity and AGB.

**Materials And Methods**

**Study area**

The study was conducted in Ranchi district, Jharkhand, Eastern India (Figure 1). Ranchi is situated between 23.13°N to 23.21°N latitude and 85.51°E to 85.54°E longitude, where the altitude varies from 400 to 700 m above mean sea level (msl). Forests of Ranchi are considered as tropical moist deciduous forests mostly dominated by S. robusta (Dipterocarpaceae), locally known as Sal forests (Champion and Seth, 1968). The study area falls under a humid subtropical climate (as per Koppen Climate Classification) and experiences 23.7°C of mean annual temperature and 397 mm precipitation at an average elevation of 650 m leading to pleasant climatic conditions.

**Vegetation sampling and analyses**

We carried out a comprehensive, and comparative evaluation of tree species diversity, stand basal area, density, and AGB through stratified random sampling to survey 92 plots each of 0.5 ha Sal forests of Ranchi during September 2016 to October 2018. Location of transects was decided based on grid generation technique following Kumar and Saikia (2020). Girth at breast height (1.37 m above ground) and height of all individual trees (≥10 cm GBH) was measured using measuring tape and range finder in each transect, respectively. GPS locations of each transect at both starting and ending points were also
collected to prepare the spatial maps of different plant diversity attributes. Community parameters such as density, basal area were determined according to Misra (1968), and diversity attributes (vegetation indices) including Margalef's index of species richness (Dmg) (Margalef, 1958), Menhinick's index of species richness (Dmn) (Whittaker, 1977), Shannon-Wiener diversity index (H') (Magurran, 1988), Simpson's index (CD) (Simpson, 1949), Pielou's evenness index (E) (Pielou, 1966), and effective number of species (ENS) (Jost, 2006) were calculated using standard formula.

The nondestructive method of biomass estimation was used to determine the AGB of all documented trees, where the basal area, tree height, species-specific gravity and volume equations were used as inputs. The GBH data collected from the field were converted into DBH by using formula GBH/π. The volumetric equations and wood specific gravity provided by the forest survey of India (FSI, 1996) has been used for further analysis of AGB. The general equation used for the volume estimation is:

**Biomass = Volume × Wood density**

**Volume = (πd)² h**

In the present research, species-specific volumetric equations were used as mentioned in Table 1. The general equation proposed by the Ministry of Agriculture & Irrigation, Government of India (1977) was used to estimate the volume of the select species, for which species-specific volumetric equations are not available in literature. AGB to carbon conversions was performed pursuant to the guidelines established in the IPCC 2006, and postulate conversion formula to estimates carbon from AGB:

**C_p = AGB × CF**

Where, **C_p = carbon stock (Mg C ha⁻¹)**,

AGB = above-ground dry biomass (Mg ha⁻¹),

CF = carbon fraction (Mg C Mg⁻¹ dry matter).

For tree vegetation, Carbon Fraction (CF) value fixed 0.47 Mg C Mg⁻¹ (IPCC, 2006).

Various plant diversity attributes were linked with transect location and spatially correlated in GIS to deduce the control of AGB over plant diversity attributes. Statistical analyses were performed with SPSS (Version 20) and maps were prepared by using ArcGIS version 10.3.

**Results And Discussions**
Spatial pattern of above-ground biomass (AGB) and carbon stock (Cp)

Field-based AGB estimates, though time and cost ineffective, are vital to characterizing forest ecosystems and to assess the potential production of tropical forests (Behera et al., 2017). The total AGB and Cp of all studied *Sal* forests were 410.69 Mg ha\(^{-1}\), and 193.06 Mg C ha\(^{-1}\) respectively, which is higher than the AGB of *Sal* plantation forest of Meghalaya, Northeast India (406 Mg ha\(^{-1}\)) (Baishya et al., 2009) as well as *Sal* forests of the Himalayas (78 to 378 Mg ha\(^{-1}\)) (Gautam et al., 2011). The present record of AGB is within the reported range (150 to 698 Mg ha\(^{-1}\)) of various tropical forests of the world (Brown and Lugo, 1982; Shrestha et al., 2000; Terakunpisut et al., 2007) as well as comparable with the reported range (28.1 to 330.87 Mg ha\(^{-1}\)) of various tropical deciduous forests of India (Ranawat and Vyas, 1975; Singh and Singh, 1981; Negi et al., 1995; Salunkhe et al., 2016) (Table 2). The forest wise AGB and Cp of tree species in different studied *Sal* forests were ranged from 0.19 to 24.75 Mg ha\(^{-1}\) (mean 4.46 ± 0.45 SE) and 0.09 to 11.63 Mg C ha\(^{-1}\) (mean 2.10 ± 0.21 SE) respectively. AGB (24.75 Mg ha\(^{-1}\)) and Cp (11.63 Mg C ha\(^{-1}\)) were maximum at Chirua, Kanke (JH019) and minimum (0.19 Mg ha\(^{-1}\) and 0.09 Mg C ha\(^{-1}\) respectively) at Agartoli, Angara (JH016) (Table 3). The spatial pattern of AGB showed that maximum studied forests (65 %) had very low AGB (<5.00 Mg ha\(^{-1}\)) followed by low AGB (5.01 to 10.00 Mg ha\(^{-1}\)) forests (25 %), moderate AGB (10.01 to 15.00 Mg ha\(^{-1}\)) forests (7 %), high AGB (15.01 to 20.00 Mg ha\(^{-1}\)) forests (2 %) and only one forests (1 %) had very high AGB (>20 Mg ha\(^{-1}\)) located in the northwest corner of Ranchi. The carbon sequestration potential of forests depends on forest type, age of forest, and age of trees, as well as its basal cover and density (Terakunpisut et al., 2007). Species wise AGB ranged from 0.001 to 7074.94 Mg ha\(^{-1}\) (mean 106 ± 71 SE) and Cp ranged from 0.0005 to 3325.22 Mg C ha\(^{-1}\) (mean 49.76 ± 33.54 SE) in *Sal* forests of Ranchi. Out of 103 recorded tree species, *Shorea robusta* had the highest AGB, and Cp (7074.94 Mg ha\(^{-1}\), and 3325.22 Mg C ha\(^{-1}\)) followed by *Madhuca longifolia* (1875.67 Mg ha\(^{-1}\) and 881.5649 Mg C ha\(^{-1}\)), *Diospyros melanoxylon* (1014.12 Mg ha\(^{-1}\) and 476.63 Mg C ha\(^{-1}\)), *Semecarpus anacardium* (221.81 Mg ha\(^{-1}\) and 104.25 Mg C ha\(^{-1}\)), *Syzygium cumini* (99.80 Mg ha\(^{-1}\) and 46.90 Mg C ha\(^{-1}\)), and *Buchanania cochinchinensis* (84.43 Mg ha\(^{-1}\) and 39.68 Mg C ha\(^{-1}\)) (Table 4). More diverse plant communities have a higher chance of including highly productive species that dominates the community, as *S. robusta* dominated the whole AGB in *Sal* mixed tropical moist deciduous forest in the upper Gangetic plains adjoining Himalayan foothills in Uttar Pradesh, India (Behera et al., 2017). Among all the tree species, *S. robusta* individually shared 64.87 % of the total AGB and only three species (*S. robusta, M. longifolia* and *D. melanoxylon*) had AGB >1000 Mg ha\(^{-1}\) and shared 93.40 % of the total AGB. Most of the tree species (65 tree species) (63.11%) had AGB <1 Mg ha\(^{-1}\), and 34 species (33.01 %) had AGB between 1 to 100 Mg ha\(^{-1}\).

On the other hand, AGB in different regions of Ranchi ranged from 0.90 to 111.74 Mg ha\(^{-1}\) (mean 6.21 ± 0.45 SE) and the highest AGB recorded in Namkum with 111.74 Mg ha\(^{-1}\) (mean 6.21 ± 0.45) followed by Kanke with 50.56 Mg ha\(^{-1}\) (mean 5.62 ± 0.45 SE), Burmu with 42.85 Mg ha\(^{-1}\) (mean 4.46 ± 0.45 SE),
Tamar 40.21 Mg ha\(^{-1}\) (3.09±0.41 SE), and the lowest AGB was recorded in Ormanjhi (0.90 Mg ha\(^{-1}\)). Tree biomass in forests vary with forest type, species composition, stand age, size class of trees, site conditions, rainfall pattern, edaphic factors and altitude (Sharma et al., 2011; Zhao et al., 2014; Cao et al., 2018). Similarly, highest carbon stock was recorded in Namkum with 52.52 Mg C ha\(^{-1}\) (12.26 ± 0.26 SE) followed by Kanke with 23.76 Mg C ha\(^{-1}\) (2.09 ± 0.21SE), Burmu with 20.14 Mg C ha\(^{-1}\) (2.53 ± 0.58 SE), Tamar with 18.90 Mg C ha\(^{-1}\) (2.53 ± 0.58 SE), Bero 18.50 Mg C ha\(^{-1}\) (2.61 ± 0.47 SE), and the lowest Cp was recorded in Rahe (0.21 Mg C ha\(^{-1}\)) (Table 5). Maximum AGB and Cp in Namkum mainly due to greater basal area 3344.54 m\(^2\) ha\(^{-1}\) (185.80 ± 21.74 SE) and maximum numbers of sampled transects (18) as compared to other regions of Ranchi.

The total basal area as well as density of trees in all studied Sal forests were 144.63 m\(^2\) ha\(^{-1}\) and 515 ind. ha\(^{-1}\) respectively. Species wise basal area of trees ranged from 0.0002 to 120.81 m\(^2\) ha\(^{-1}\) (mean 1.40 ± 1.17 SE) and density ranged from 0.02 to 416 ind. ha\(^{-1}\) (mean 5 ± 4.04 SE). S. robusta had maximum basal cover (120.81 m\(^2\) ha\(^{-1}\)) as well as density (416 ind. ha\(^{-1}\)) among all tree species and is the reason for its maximum AGB and Cp. However, no similar trends were observed in all other trees. B. cochinchinensis had the second largest basal area (4.63 m\(^2\) ha\(^{-1}\)) followed by Mangifera indica (3.06 m\(^2\) ha\(^{-1}\)), D. melanoxylon (1.64 m\(^2\) ha\(^{-1}\)) and Terminalia arjuna (1.48 m\(^2\) ha\(^{-1}\)). While, D. melanoxylon had the second highest density (23 ind. ha\(^{-1}\)) followed by B. cochinchinensis (15 ind. ha\(^{-1}\)) (Table 4). On the other hand, forest wise stand basal area and stand density of trees ranged from 30.72 to 367.84 m\(^2\) ha\(^{-1}\) (mean 135.28 ± 7.24 SE), and 136 to 1712 ind. ha\(^{-1}\) (mean 515 ± 34.16 SE) respectively. Maximum tree density (1712 ind. ha\(^{-1}\)) was recorded in Paina Pahar, Lapung (JH059) and minimum (136 ind. ha\(^{-1}\)) in Silway, Namkum (JH01), while, basal area of trees was highest (367.84 m\(^2\) ha\(^{-1}\)) in Harbul, Namkum (JH061), and minimum (30.72 m\(^2\) ha\(^{-1}\)) in Koijam, Burmu (JH029) (Table 2). Maximum studied forests (30 %) had moderate basal cover (100.1 to 150 m\(^2\) ha\(^{-1}\)) followed by high basal cover (150.1 to 200 m\(^2\) ha\(^{-1}\)) forests (24 %), while maximum studied forests (47 %) had less tree density (150 to 300 ind. ha\(^{-1}\)) followed by very less tree density (<150 ind. ha\(^{-1}\)) forests (27 %), moderate tree density (301 to 450) forests (13 %) and rest 14 % forests had high and very high tree density (>450 ind. ha\(^{-1}\)).

Spatial pattern of plant diversity attributes

A total of 103 tree species belonging to 81 genera and 33 families are recorded in 46 ha study plots, which is lower than the earlier records from moist Sal forests of northern West Bengal (134 trees) (Kushwaha and Nandy, 2012), and tropical deciduous forest in Mudumalai Wildlife Sanctuary (124 trees in 6.1 ha sampled plots) (Reddy and Ugle, 2008), but quite higher than Western Terai Sal forests of Nepal (28 trees) (Timilsina et al., 2007). Fabaceae (20 spp.) is the most species rich family followed by Moraceae (08 spp.), Euphorbiaceae (07 spp.) and 14 families are monotypic. On the other hand, Ficus (06 spp) is the most species rich genera followed by Terminalia (05 spp.) and 68 genera are monotypic. Tree diversity ranged from 01 to 27 species (mean 12 ± 0.60 SE) in all 92 studied Sal forests of Ranchi. Tree
diversity in terms of Shannon-Weiner diversity index ($H'$) was ranged from 0.45 to 2.76 (mean $1.65 \pm 0.48$ SE), which is falls within the range (0.62–3.96) reported by earlier workers for various tropical deciduous forests of India (Tripathi and Singh, 2009; Naidu and Kumar, 2016; Sahoo et al., 2020). Maximum studied forests (42 %) had moderate tree diversity ($H'$: 1.51 to 2.00) followed by less diversity ($H'$: 1.00 to 1.50) forests (28 %), high diversity ($H'$: 2.01 to 2.50) forests (17 %), very less diversity ($H'$: <1.00) forests (9), and very high diversity ($H'$>2.50) forests (3 %). The possible reason of lower $H'$ in the studied $Sal$ forests may possibly be due to anthropogenic disturbances resulting in habitat destruction, which leads to the survival of less number of tree species and their individuals. The highest tree diversity in terms of Shannon $H'$ (2.76) was recorded in $Sal$ forest located at Koijam, Burmu (JH029) and the highest E (0.87) was recorded in Siram, Burmu (JH030). The values of $H'$, CD, E, Dmg, Dmn, and ENS do not follow a definite pattern in all studied $Sal$ forests of Ranchi (Table 2). Evenness index also known as species equitability ranged from 0.25 to 0.87 (mean $0.68 \pm 0.11$ SE), while ENS ranged from 2 to 16 (mean $6 \pm 0.30$). ENS denotes the amount of diversity directly compared with the within-community, and among community components, provides more interpretable, and comparable assessments of biodiversity as compared to species richness, $H'$, and CD (Jost, 2007). It is the true diversity of community used to assess species diversity on the basis of $H'$, and responds to either known alteration in assemblage or environmental variables (Cao and Hawkins, 2019). On the other hand, CD ranged from 0.10 to 0.72 (mean $0.34 \pm 0.01$), which was within the reported range of CD (0.19 to 0.99) for forest vegetation (Whittaker, 1965). Lower CD (0.10) in few studied $Sal$ forests (JH029, and JH030) indicate that dominance is shared by more than one species, and values of CD were lower in contrast with high species diversity ($H'$) (2.76 and 2.74) as species diversity behaves inversely to the index of dominance (CD) (Odum, 1971). Dmg ranged from 0.17 to 11.68 (mean $2.06 \pm 0.15$) and Dmn ranged from 0.11 to 2.03 (mean $0.78 \pm 0.04$) in various studied $Sal$ forests of Ranchi. The species richness in terms of Dmg and Dmn were 10.23 and 0.68 respectively for all studied $Sal$ forests of Ranchi.

On the basis of $H'$ and E, $Sal$ forests were classified into highly diverse (HD) with $H'$ > 2.00, moderately diverse (MD) ($H' = 1.6$–2.0), low diversity (LD) ($H'<1.6$) forests and highly even (HE) with E > 0.75, moderately even (ME), E = 0.6–0.75, and poorly even (LE) E<0.06 forests. Further, unique combination of $H'$ and E (HD-LE, HD-ME, HD-HE, MD-LE, MD-ME, MD-HE, LD-LE, LD-ME, LD-HE) was used to classify all the studied $Sal$ forests of Ranchi (Table 3). Grouping of $H'$-E at different nine combinations illustrates that only 03 (3.26%) studied forests (JH003, JH070, and JH077) showed extreme tree diversity with high $H'$ and low E (ETDFs). Similarly, very high tree diversity forests with high $H'$ and moderate E (VHTDFs) was recorded in 11 (11.96 %) studied forests and high tree diversity forests with high $H'$ and high E (HTDFs) was recorded in 04 (4.35 %) studied forests, while only one studied forests (JH002) classified as tree diversity forests with moderate $H'$ and low E (TDFs) (Figure 2).

**Relationship between plant diversity attributes and AGB**

The relationships between tree basal cover, density, plant diversity attributes (Dmg, Dmn, $H'$, CD, ENS, and E), and AGB was documented in $Sal$ forests of Ranchi. Correlation of basal area with AGB was positive,
and statistically significant ($r = 0.71, p<0.05$) indicating that basal area is a major indicator of AGB. Strong relationships between AGB and basal area have also been reported by several workers in various types of forests (Cannell, 1984; Rai and Proctor, 1986). Likewise, high AGB indicate high Cp, so correlation between AGB and Cp was positive and highly significant ($r = 1.00, p<0.01$). AGB showed insignificant, negative correlation with tree density ($r = -0.17$) indicating that forests with higher tree density have reduced AGB. Generally, in dense forests, the availability of soil nutrients and water, due to high intraspecific competition cannot properly availed by plants for their growth and development may be the reason of lower AGB in higher tree density forests. Inverse relationship of total tree density with AGB was also observed in Terai *Shorea* forest and *Shorea-Terminalia* forest of south-western part of Nepal (Giril *et al.*, 1999), while a strong positive relationship of density and AGB was observed in Katerniaghan Wildlife Sanctuary, a tropical moist deciduous forest in the upper Gangetic plains adjoining Himalayan foothills in Uttar Pradesh, India (Behera *et al.*, 2017). Again, basal area had insignificant negative relationship with $H'$ ($r = -0.13$), ENS ($r = -0.11$) and Dmg ($r = -0.004$), while it has significant negative correlation with $E$ ($r = -0.27, p<0.01$) and Dmn ($r = -0.26, p<0.05$). On the other hand, a positive linear relationship had been observed between diversity and total tree basal area (a substitute for biomass) in tropical deciduous forests in India (Sagar and Singh, 2006). The highest AGB (>20 Mg ha$^{-1}$) was recorded at high basal area (>160 m$^2$/ha) as AGB increases with the increase in basal area, but no similar trends had been followed by all studied *Sal* forests (*Figure 3a*). Similarly, very low density forests (<150 ind. ha$^{-1}$) (*Figure 3b*) had highest AGB (>20 Mg ha$^{-1}$), as well as highest species diversity (>2.0) (*Figure 3c*). A highly significant positive correlations of AGB with $H'$ ($r = 0.58, p<0.01$), Dmg ($r = 0.31, p<0.01$), Dmn ($r = 0.49, p<0.01$), and ENS ($r = 0.57, p<0.01$) were observed in the present study, while AGB-E relationship was statistically significant and positive ($r = 0.26, p<0.05$) (*Table 7, Figure 4a-f*), possibly due to continual disturbance does not allow biomass to concentrate in only the strongest competitors. AGB increased with increase in tree diversity, as high species richness helps in increased nutrient use efficiency (Ruijven and Berendse, 2005). On the other hand, species richness is highly correlated with other plant diversity attributes and a high correlation exists between $H'$ and species richness across tropical forests (Gentry, 1988). The present study also recorded highly significant positive correlation of $H'$ with Dmg ($r = 0.49, p<0.01$), and Dmn ($r = 0.84, p<0.01$). The tropical deciduous forests in India experience frequent, large-scale human disturbances from mining, power generation, grazing, tree felling, and extraction of forest resources (Kumar and Saikia, 2020). Disturbance regimes differ greatly among tropical forests as they experience more frequent or smaller scale disturbances and may account for differences in species richness-AGB relationships in tropical forests (Phillips *et al.*, 1994). In conformity with the present study, positive relationships have been observed between plant diversity/richness and AGB in various forests (Caspersen and Pacala, 2001; Erskine *et al.*, 2006; Houle, 2007). However, negative (Lugo, 1992, Wardle *et al.*, 1997), and no relationships (Vila *et al.*, 2003) between plant diversity/richness and AGB have also been documented in forests. Although results are not consistent regarding the species richness-AGB relationship in forests, trees grow faster and attain greater biomass in forests (Erskine *et al.*, 2006; Potvin and Gotelli, 2008). Therefore, positive relationships may be the most obvious expectation for the species richness-AGB relationship in forests. High and positive correlation of AGB with $H'$ and ENS signifies the diversity of tree species in studied forests did have major effects on growth and development by intraspecific competition.
among the species. However, AGB was negatively correlated with CD (r = -.57, p<0.01) may be because of CD inversely related to H'. The negative CD-AGB relationships suggest that a few species become more dominant at high biomass, instead of the biomass being distributed evenly among all species (Vance-Chalcraft et al., 2010).

Conclusions

The present study showed that tree density, basal area, AGB and Cp used to be varied in different studied forests as well as tree species. The higher basal cover (144.63 m² ha⁻¹), and tree density (515 ind. ha⁻¹) in all studied forests supports higher AGB (410.69Mg ha⁻¹), and Cp (193.06Mg C ha⁻¹) in the region. S. robusta being the most dominant tree species, adapts better in sub-tropical climate conditions and has the highest AGB (7074.94 Mg ha⁻¹) and Cp (3325.23 Mg C ha⁻¹). However, attention should be given for the conservation of other native tree species like Bauhinia variegata (0.015 Mg ha⁻¹, and 0.007 Mg C ha⁻¹), Sterculia urens (0.021 Mg ha⁻¹, and 0.10 Mg C ha⁻¹), Azadirachta indica (0.256 Mg ha⁻¹, and 0.120 Mg C ha⁻¹), and Bauhinia purpurea (0.280 Mg ha⁻¹ and 0.132 Mg C ha⁻¹) with low AGB and Cp as these species have also lower density as well as basal cover in the studied Sal forests of Ranchi. Positive, and statistically significant correlation (r = 0.81, p<0.05) of basal area with AGB indicates that basal area is a major contributor of AGB. Furthermore, it was found that the carbon storage potential in the forests is influenced by tree basal area, density, and diversity attributes (Dmg, Dmn, CD, H', ENS, and E). Estimation of forest Cp enables us to assess the amount of carbon loss during deforestation or the amount of carbon stored during forest regeneration. The present study will directly help in studying the response of climate change on ecosystem productivity, energy and nutrient flow, and for assessing the patterns of carbon sequestration in Indian forests under global climate change. Further research is needed to depict the long-term effects of tree harvesting to maintain their productivity and soil fertility status in relation to the sustainability of Sal dominated forests of Ranchi, Jharkhand, Eastern India.

Funding

This is the outcome of Science and Engineering Research Board (SERB), New Delhi, Govt. of India sponsored R & D project entitled ‘Status, Distribution and Composition of Sal Forests of Ranchi, Jharkhand, Eastern India in relation to Microclimatic as well as Edaphic Conditions’ sanctioned to Dr. Purabi Saikia under SERB-Young Scientist Scheme (Ref. No. YSS/2015/000479 dated 12th January 2016).

Authors’ contributions

**RK** participated in the field data collection, analyses, and interpretation, and drafted the manuscript; **AK** helped in analyses as well as preparation of maps and also in finalizing the MS; **PS** conceived the study, helped in species identification and also finalized the manuscript. All authors read and approved the final manuscript.

Acknowledgements

Authors are thankful to Science and Engineering Research Board (SERB), New Delhi, Govt. of India for financial support for the project ‘Status, Distribution and Composition of Sal Forests of Ranchi, Jharkhand, Eastern India in relation to Microclimatic as well as Edaphic Conditions’ (Ref. No. YSS/2015/000479 dated 12th January 2016). The support and assistance provided by the Jharkhand State Forest Department, Ranchi and the local people involved during the field survey are highly acknowledged.

Table 6: Classification of studied *Sal* forests of Ranchi, Jharkhand, Eastern India, based on the Shannon-Weiner diversity ($H'$) and evenness index ($E'$) combination.

| Shannon-Weiner diversity ($H'$) - Evenness index ($E'$) combination | Unique name for $H'$ and $E$ combination | Interpretation Code | No. of studied forests | % |
|---|---|---|---|---|
| HD-LE | Extreme tree diversity forests with high $H'$ and low $E$ | ETDFs | 03 | 3.26 |
| HD-ME | Very high tree diversity forests with high $H'$ and moderate $E$ | VHTDFs | 11 | 11.96 |
| HD-HE | High tree diversity forests with high $H'$ and high $E$ | HTDFs | 04 | 4.35 |
| MD-LE | Tree diversity forests with moderate $H'$ and low $E$ | TDFs | 01 | 1.09 |
| MD-ME | Moderate tree diversity forests with moderate $H'$ and moderate $E$ | MTDFs | 23 | 25.00 |
| MD-HE | Low tree diversity forests with moderate $H'$ and high $E$ | LTDFs | 09 | 9.78 |
| LD-LE | Highly low tree diversity forests with low $H'$ and low $E$ | HLTDFs | 04 | 4.35 |
| LD-ME | Very low tree diversity forests with low $H'$ and moderate $E$ | VLTDFs | 25 | 27.17 |
| LD-HE | Extremely low tree diversity forests with low $H'$ and high $E$ | ELTDFs | 12 | 13.04 |
Table 7: Pearson Correlation coefficient among various community parameters, Margalef’s index of species richness (Dmg), Menhinick’s index of species richness (Dmn), Shannon-Weiner diversity index (H’), concentration of dominance (CD), evenness index (E), effective number of species (ENS), density (ind. ha\(^{-1}\)), basal area (BA) (m\(^2\) ha\(^{-1}\)), above ground biomass (AGB) (Mg ha\(^{-1}\)), and carbon stock (Cp) (Mg C ha\(^{-1}\)) of all studied *Sal* forests of Ranchi, Jharkhand, Eastern India.

|      | Density | BA    | AGB   | Cp     | H’     | Dmg   | Dmn   | E     | ENS   |
|------|---------|-------|-------|--------|--------|-------|-------|-------|-------|
| BA   | .294**  | 1     |       |        |        |       |       |       |       |
| AGB  | -.017   | .71*  | 1     |        |        |       |       |       |       |
| Cp   | -.017   | .71   | 1.00**| 1      |        |       |       |       |       |
| H’   | -.041   | -.126 | .584**| .584** | 1      |       |       |       |       |
| Dmg  | .034    | -.004 | .310**| .310** | .494** | 1     |       |       |       |
| Dmn  | -.338** | -.259*| .493**| .493** | .841** | .513**| 1     |       |       |
| E    | -.156   | -.271*| .257* | .257*  | .398** | .239* | .418**| 1     |       |
| ENS  | -.036   | -.105 | .565**| .565** | .951** | .546**| .842**| .444**| 1     |
| CD   | .154    | .192  | -.567**| -.567**| -.927**| -.418**| -.81**| -.462**| -.848**|

N=92

**. Correlation is significant at the 0.01 level

*. Correlation is significant at the 0.05 level

Figures
Figure 1

Map of the study area showing the locations of studied transects in Sal forests of the Ranchi, Jharkhand, Eastern India.
Figure 2

Multiple combinations of Shannon-Weiner diversity index (H') with evenness index (E) of studied Sal forests of Ranchi, Jharkhand, Eastern India (ETDFs: Extreme tree diversity forests with high H’ and low E, VHTDFs: Very high tree diversity forests with high H’ and moderate E, HTDFs: High tree diversity forests with high H’ and high E, TDFs: Tree diversity forests with moderate H’ and low E, MTDFs: Moderate tree diversity forests with moderate H’ and moderate E, LTDFs: Low tree diversity forests with moderate H’ and high E, HLTDFs: Highly low tree diversity forests with low H’ and low E, VLTDFs: Very low tree diversity forests with low H’ and moderate E, ELTDFs: Extremely low tree diversity forests with low H’ and high evenness).
Figure 3

Map showing the spatial distribution and relationship of AGB with (a) basal area, and (b) density, (c) relationship of diversity and density.
Map showing spatial distribution and relationship of AGB with (a) Shannon H', (b) Dmg, (c) Dmn, (d) E, (e) ENS, and (f) CD.
