We measure the response of an elongated Bose-Einstein condensate to a two-photon Bragg pulse. If the duration of the pulse is long, the total momentum transferred to the condensate exhibits a nontrivial behavior which reflects the structure of the underlying Bogoliubov spectrum. It is thus possible to perform a spectroscopic analysis in which axial phonons with different number of radial nodes are resolved. The local density approximation is shown to fail in this regime, while the observed data agrees well with the results of simulations based on the numerical solution of the Gross-Pitaevskii equation.

PACS numbers:

The crossover between phonon and single-particle excitations in the Bogoliubov spectrum of a weakly interacting Bose gas is one of the main “textbook” concepts that can be directly tested in the case of trapped Bose-Einstein condensates. Bogoliubov quasiparticles have been already produced in elongated condensates by using two-photon Bragg scattering. For excitations with frequency \( \omega \) and wavevector \( k \), the phononic character has been checked by observing that the static structure factor \( S(k) \) is less than 1, by measuring the quasiparticle amplitudes \( u_k \) and \( v_k \), and by showing that the dispersion relation \( \omega(k) \) is linear at low \( k \).

In all of these cases, the local density approximation (LDA) has been used to adapt the Bogoliubov theory of uniform gases to the actual inhomogeneous condensates. This approach is expected to be accurate for large condensates, where the density profile varies smoothly on the scale of the excitation wavelength and the system behaves locally as a piece of uniform gas with a local Bogoliubov spectrum. This applies, for instance, to axial excitations of elongated condensates, when the wavelength of the excited states is much smaller than the size of the system along the major axis. These excitations can then be classified with a continuous wavevector \( k \). However, the finite transverse size of the condensate also produces a discreteness of the spectrum, which is ignored in LDA (see for a recent classification of normal modes in anisotropic condensates and for the limiting case of an infinite cylinder).

In this Letter we show that the response of the condensate to a Bragg pulse is indeed significantly affected by the radial degrees of freedom. In particular, if the duration of the pulse is longer than the radial trapping period, the condensate responds resonantly at the frequencies \( \omega_{n_r}(k) \) of axial quasiparticles with \( n_r \) nodes in the radial direction. By using Bragg pulses longer than in previous measurements, we resolve this multi-branch spectrum, finding good agreement with the predictions of Gross-Pitaevskii (GP) theory.

As described in Ref. \cite{4}, our condensate consists of \( N = 10^5 \) atoms of \(^{85}\)Rb, with a thermal fraction of 5\% or less. The radial and axial trapping frequencies are \( \omega_\perp = 2\pi(220\text{Hz}) \) and \( \omega_z = 2\pi(25\text{Hz}) \) respectively. The radial and axial Thomas-Fermi radii of the condensate are \( R = 3.1\mu\text{m} \) and \( Z = 27.1\mu\text{m} \).

We excite the condensate by using two Bragg beams with approximately parallel polarization, separated by an angle \( \theta \). The Bragg beams illuminate the entire condensate for a time \( t_B \). The beams have a frequency difference \( \omega \) determined by two acousto-optic modulators. If a photon is absorbed from the higher-frequency beam and emitted into the other, an excitation is produced with energy \( \hbar \omega \) and momentum \( \mathbf{k} \), where \( k = 2k_p \sin(\theta/2) \), and \( k_p \) is the photon wave number. The wave vector \( \mathbf{k} \) is adjusted to be along the \( z \)-axis. To measure a single point on the excitation spectrum \( \omega(k) \), \( k \) is fixed by \( \theta \), and \( \omega \) is varied.

The measured quantity is the total momentum transferred to the condensate along \( z \). This is obtained by switching off the trapping potential after the Bragg pulse and taking absorption images of the density distribution of the expanding condensate. In Fig. 1 we show typical results for short Bragg pulses of duration \( t_B = 1 \text{msec} \). The observed momentum \( P_z \) is plotted as a function of \( \omega \) for three different values of \( k \). In Ref. \cite{4} we made Gaussian fits to these type of curves, taking the position of the maximum to be the quasiparticle dispersion \( \omega(k) \) and showing that this dispersion was consistent with the Bogoliubov spectrum in the LDA.
alternating direction implicit algorithm, as in [14].

values. Solid lines are the results of GP simulations. The
dashed lines are the LDA predictions.

A deeper analysis of the same results can be performed
by numerically solving the GP equation for the order
parameter of the condensate \( \Phi(r, t) \) [12],

\[
\frac{i \hbar \partial}{\partial t} \Phi = \left( -\frac{\hbar^2 \nabla^2}{2m} + V + g|\Phi|^2 \right) \Phi \tag{1}
\]

where \( g = 4\pi\hbar^2 a/m \) is determined by the s-wave scattering
length \( a \). The external potential can be taken as the
sum of the harmonic confinement and the Bragg potential,

\[
V(r, t) = \frac{m}{2} (\omega_x^2 r_x^2 + \omega_z^2 z^2) + \theta(t)V_B \cos(kz - \omega t) \tag{2}
\]

where \( r_x^2 = x^2 + y^2 \) and \( \theta(t) \) is equal to 1 in the interval
0 < \( t < t_B \) and 0 outside.

The ground state at \( t = 0 \) can be found as the stationary solution of Eq. (1). Then, the time dependent GP equation can be solved at \( t > 0 \) to simulate the Bragg process [8] [13]. We take advantage of the axial symmetry of \( V \) to map the order parameter into a two-dimensional grid of points \( N_1 \times N_z \) (typically, 64 \times 1024) and evolve it by means of a Crank-Nicholson differencing method with alternating direction implicit algorithm, as in [14].

The momentum transferred to the condensate can be calculated from \( \Phi \) through the definition \( P_z = (-i\hbar/2) \int d\mathbf{r} \Phi^* \partial_z \Phi + \text{c.c.} \). Fig. 1 shows good agreement between the results of the GP simulations (solid lines) and the experimental data, for short pulses. The strength \( V_B \) in the GP equation is used as a free parameter, so the comparison is restricted to the position and shape of the peak. In principle, \( V_B \) could be determined by using the experimental parameters for the power, area, and direction of polarization of the two laser beams, but this estimate might be affected by a significant uncertainty.

The LDA curves (dashed lines in Fig. 1), which are obtained by using the local Bogoliubov spectrum to calculate \( P_z(k, \omega) \) in the linear response regime as in [8], are also reasonably close to the GP predictions. For shorter \( t_B \) we checked that the accuracy of the LDA is even better, as discussed in [3].

A rather different situation is found for longer pulses, with \( t_B \) of the order of the radial trapping period (about 4.5 msec) [4]. Fig. 2 shows the momentum transferred in the GP simulations (solid curves) for various time durations \( t_B \). The lowest curve, after 1 msec, is a broad peak as in Fig. 1, close to the LDA (dashed curves). For later times however, a multi-peak structure appears, strongly deviating from LDA. We find a similar behavior for all values of \( k \) in our simulations, and for a wide range of intensities \( V_B \).

The momentum is transferred in the Bragg pulse, for \( k = 3.1 \text{m}^{-1} \). Solid curves are the results of GP simulations with \( V_B = 0.2\hbar\omega_\perp \) plotted at various times. Starting with the lowest solid curve, \( t_B \simeq 1, 2, 3, 4, 5 \) and 6 msec. Dashed curves are the corresponding LDA predictions. The arrows indicate the GP predictions for the frequencies of the normal modes of the condensate, having 0, 1 and 2 radial nodes and the same axial wave vector \( k \).

Figures 3a and 3b show measurements of \( P_z \) for \( k = 1.4 \text{m}^{-1} \) and 3.1 \text{m}^{-1} respectively, with long pulses of duration 10 msec and 6 msec, respectively. The intensities of the Bragg beams are adjusted so that the number of excitations created on the Bragg mode is no more than roughly 25% of the number of atoms in the condensate. Each point in Fig. 3 is an average of about 5 measurements. The results of GP simulations are indicated by the upper solid curves, which are obtained by choosing \( V_B = 0.2\hbar\omega_\perp \) and 0.35\hbar\omega_\perp for Figs. 3a and 3b, respectively. Both the measurements and the GP simulations
show multiple peaks, due to the excitations of quasiparticles with different \( n_r \).

In Fig. 3, we see good agreement between the locations of the peaks in the experimental and GP results, but the experimental peaks are broader due to noise. The major source of noise is the sloshing of the condensate in the trap. Specifically, sloshing of speed \( v_\omega \) in the axial direction yields a Doppler shift in the light potential of frequency \( k v_\omega/2\pi \). This gives a frequency noise that significantly broadens the peaks of \( P_z \). However, we can reduce this noise by estimating the velocity of the condensate in the trap at the end of the Bragg pulse from its position in the time-of-flight image, and by explicitly adding the corresponding Doppler shift to the applied \( \omega \) in the laboratory frame. This correction requires that the Bragg pulse be much shorter than the axial trap period (40 msec). This requirement is sufficiently met by the 6 msec pulses employed for \( k = 3.1 \mu m^{-1} \). Therefore, the data points of Fig. 3b contain the correction.

We verify that the multi-peak structure reflects the fundamental normal modes composing the multi-branch spectrum, and does not depend significantly on the intensity \( V_B \). The lower curves of Figs. 3a and 3b correspond to the same simulations as the upper curves, but with \( V_B \) reduced by a factor 10. In this case, the system is excited in the linear response regime. The momentum transferred is two order of magnitude smaller, but the resulting curves have peaks at the same locations as for larger \( V_B \). Furthermore in the case of \( k = 3.1 \mu m^{-1} \) we repeat the measurement and simulation of Fig. 3b with an intensity 30\% greater and find peaks again at the same location. This means that nonlinear effects are not crucial in our observations. Nevertheless, they might be interesting. Indeed, looking at Fig. 3a one notices small differences between the lower and upper curves, for small and large \( V_B \) respectively. The curve for large \( V_B \) displays two side peaks around the main peak at 0.4 kHz. These side peaks, whose shape significantly depends on \( t_B \), are not visible in the linear regime of the small \( V_B \) curve and might be due to nonlinear effects. Similar effects were found by a one-dimensional simulation in Ref. [10].

Now we use the GP equation to directly find the multi-branch Bogoliubov spectrum of the condensate. Specifically, we analyze the oscillations in the condensate density induced by the Bragg process. In the GP simulation we let the condensate freely oscillate in the trap after the Bragg pulse and we perform a Fourier analysis of the density variations. This analysis shows that for each \( k \) and \( \omega \), the density oscillates as a superposition of modes of frequency \( \omega_n(k) \), which are excited by the Bragg potential in Eq. (2) due to the inhomogeneity of the condensate in the radial direction. For symmetry reasons, only modes with azimuthal angular momentum \( m = 0 \) are excited. The calculated frequencies are shown as open circles in Fig. 4 [17]. The lowest branch corresponds to Bogoliubov axial modes with no radial nodes. The second branch has one radial node; it starts at \( 2\omega_\perp \) for \( k = 0 \), where it corresponds to a purely radial breathing mode. The third branch has two nodes [18].

In the limit of small oscillations, all these states coincide with the solutions of the linearized GP equation, i.e., the generalization of the Bogoliubov equations to inhomogeneous condensates. For an infinite cylinder these solutions were calculated in Ref. [10] and, in the hydrodynamic limit (\( k \) much smaller than the inverse healing length \( \xi^{-1} \)), in Ref. [11]. For \( k \ll \xi^{-1} \), our multi-branch spectrum turns out to be very close to the spectrum predicted in Ref. [11], indicated by dashed lines in Fig. 4 (also see Fig. 1 of Ref. [11]). \( \xi^{-1} \) is indicated by a dotted line in Fig. 4.
The calculated normal mode frequencies are shown as arrows on the $\omega$ axes in Figs. 2 and 3. Both the theoretical curves and the experimental results clearly show that the momentum is resonantly transferred to the condensate when the Bragg frequency is close to the Bogoliubov branches.

The locations of the measured peaks of Fig. 3 are also shown as filled circles in Fig. 4. The good agreement between these measured peaks and the simulated spectrum (open circles) identifies the peaks in the observed spectrum as being axial quasiparticles with $n_r$ radial nodes. Bragg pulses can indeed be used to perform high resolution spectroscopy of the multi-branch Bogoliubov spectrum of trapped condensates in a regime where the LDA is not applicable.

In conclusion, we have used long Bragg pulses to spectroscopically measure the first and zeroth order radial modes in the phonon spectrum of a BEC. These high-resolution measurements agree well with simulations of the Gross-Pitaevskii equation. The local density approximation fails to reproduce these multiple radial modes.

The technique of long Bragg pulses could also be used to resolve inherent dissipation mechanisms, such as inhomogeneous broadening and coupling between modes, including Beliaev and Landau damping. The technique could be particularly effective if the inhomogeneous broadening could be overcome, by means of echo techniques, or the use of non-quadratic optical dipole traps. Finally, very sensitive GP simulations could be used in combination with long pulses, to carefully study non-linear dynamics.

[17] The calculated frequencies have an uncertainty of the order of $0.05$ kHz, due to the finite time interval used for the Fourier analysis.
[18] In this range of $k$ only three branches are visible in the Fourier spectrum. The efficiency of the Bragg perturbation (8) in exciting higher branches increases with $k$. 

FIG. 4: Excitation frequencies vs. $k$ for a trapped BEC. The open circles are the frequencies of the normal modes with $n_r = 0, 1, 2, \ldots$ nodes in the radial direction, as calculated from the GP equation. The filled circles are the position of the maxima of the main peaks in $P_z$ for the long-pulse measurements of Fig. 3. The dashed lines are the prediction for an infinite cylinder with $k \ll \xi^{-1}$. The dotted line indicates the inverse healing length.
