Abstract

The likelihood function represents statistical evidence in the context of data and a probability model. Considerable theory has demonstrated that evidence strength for different parameter values can be interpreted from the ratio of likelihoods at different points on the likelihood curve. The likelihood function can, however, be unknown or difficult to compute; e.g. for genetic association studies with a binary outcome in large multi-generational families. Composite likelihood is a convenient alternative to using the real likelihood and here we show composite likelihoods have valid evidential interpretation. We show that composite likelihoods, with a robust adjustment, have two large sample performance properties that enable reliable evaluation of relative evidence for different values on the likelihood curve: (1) The composite likelihood function will support the true value over the false value by an arbitrarily large factor; and (2) the probability of favouring a false value over a true value with high probability is small and bounded. Using an extensive simulation study, and in a genetic association analysis of reading disability in large complex pedigrees, we show that the composite approach yields valid statistical inference. Results are compared to analyses using generalized estimating equations and show similar inference is obtained, although the composite approach results in a full likelihood solution that provides additional complementary information.
Keywords: Composite likelihoods; Correlated binary data; Family data; Genetic association analysis; The likelihood paradigm.
1 Introduction

Genetic association studies have identified many genes or markers that contribute to disease susceptibility (Welter et al., 2014). Genetic data from families are often collected for the purpose of linkage analysis, however this pedigree data can also be used for fine-mapping studies using population based association analysis (Browning et al., 2005). When related individuals are involved in the analysis, GEE or generalized linear mixed effects models are commonly implemented in a frequentist framework (Thornton, 2015). A comprehensive comparison of several methods, namely, GEE, generalized linear mixed model, and a variance component model, for genome-wide association studies was conducted in Chen et al. (2011) and, after consideration for low disease prevalence and rare genetic variants, linear mixed models were the only approach that resulted in valid type I error and adequate statistical power in the majority of cases. However, this method does not have an odds ratio interpretation for the regression coefficients and is computationally challenging. GEE is computationally more efficient and the inflation in type I error for the GEE is due to small sample size that can be avoided by using a jackknife variance estimator. However, the GEE is an estimation equation approach and does not allow for full likelihood interpretation. In the next section, we review the likelihood paradigm (Royall, 1997), a paradigm for statistical inference directly from the likelihood (or pseudo-likelihood) function that provides an alternative approach to this problem.

1.1 Likelihood Paradigm

The likelihood paradigm uses likelihood functions to represent the statistical evidence generated in a study about the unknown parameter(s) of interest and uses likelihood ratios to measure the strength of statistical evidence for one hypothesis versus another. Suppose we observe $y$ as a realization of a random variable $Y$ with a probability distribution $\{f(\cdot;\theta), \theta \in \Theta\}$ where $\theta$ is a fixed dimensional parameter. The Law of Likelihood (Hacking, 1965) states: ‘if hypothesis $H_1$ implies that the probability that a random variable $Y$ takes the value $y$ is $f_1(y)$, while hypothesis $H_2$ implies that the probability is $f_2(y)$, then the observation $Y = y$ is evidence supporting $H_1$ over $H_2$ if and only if $f_1(y) > f_2(y)$, and the likelihood ratio, $f_1(y)/f_2(y)$, measures the strength of that evidence’. Then, for $L(\theta) \propto f(y;\theta)$, $L(\theta_1)/L(\theta_2)$ measures the
strength of evidence in favour of \( H_1 : \theta = \theta_1 \) relative to \( H_2 : \theta = \theta_2 \). We have strong evidence in favour of \( H_1 \) versus \( H_2 \) if \( L(\theta_1)/L(\theta_2) > k \), strong evidence in favor of \( H_2 \) versus \( H_1 \) if \( L(\theta_1)/L(\theta_2) < 1/k \) and we have weak evidence if \( 1/k < L(\theta_1)/L(\theta_2) < k \) that is, the data did not produce sufficiently strong evidence in favor of either hypothesis. This is an undesirable result since it tells us the data provided are not sufficient to produce strong evidence, we need to increase the sample size. Another undesirable result is to observe strong evidence in favour of the wrong hypothesis, that is, observing misleading evidence, which also can be minimized by increasing the sample size. Moreover, below we see that the probability of observing misleading evidence is bounded. The choice of \( k \) can be determined in the planning stage such that the probability of observing weak and misleading evidence is small. For discussions on benchmarks for \( k \), see Royall (1997, p.11).

The probability of getting misleading evidence, a function of \( k \) and \( n \), is denoted by \( M_1(n,k) = P_1(L(\theta_2)/L(\theta_1) \geq k) \), where \( P_1 \) indicates the probability is taken under the correct model hypothesized in \( H_1 \). Royall (2000) shows that this probability is described by a bump function, \( P_1(L(\theta_2)/L(\theta_1) \geq k) \rightarrow \Phi(-c/2 - \log(k)/c) \), where \( k > 1, \Phi \) is the standard normal distribution function and \( c \) is proportional to the distance between \( \theta_1 \) and \( \theta_2 \), where \( c = \Delta \sqrt{n}/\sigma \). When the distance \( \Delta \) is measured in units of the standard error, the probability of misleading evidence is independent of the sample size at a fixed \( c \) (Figure 1). Figure 1 indicates that the probability of observing misleading evidence is 0 when the distance between the two hypothesized values is very small and corresponds to high probabilities of observing weak evidence. The probability of observing misleading evidence tends to 0 when the distance between the two hypothesized values increases and, regardless of the sample size, the bump function is maximized at \( \Phi(-\sqrt{2\log k}) \) when \( \Delta = (2\log k)^{1/2} \) and this is the best possible bound.
To ensure reliable inferential properties for the likelihood paradigm, two important performance properties are required (Royall (2000), Royall and Tsou (2003)). Let \( L(\theta) \) be the likelihood function where \( X_1, \ldots, X_n \) are iid with a smooth probability model \( f(\cdot; \theta) \) for \( \theta \in \mathcal{R} \). Then 1) for any false value \( \theta \neq \theta_0 \), the evidence will eventually support \( \theta_0 \) over \( \theta \) by an arbitrarily large factor: \( P_0(L(\theta_0)/L(\theta) \to \infty \text{ as } n \to \infty) = 1 \), and 2) in large samples, the probability of misleading evidence, as a function of \( \theta \), is approximated by the bump function, \( P_0(L(\theta)/L(\theta_0) \geq k) \to \Phi(-c/2 - \log(k)/c) \) where \( k > 1 \), \( \Phi \) is the standard normal distribution function and \( c \) is proportional to the distance between \( \theta \) and \( \theta_0 \). The results can be extended to the case where \( \theta \) is a fixed dimensional vector parameter. The first property implies that the probability of getting strong evidence in favor of the true value goes to 1. This implies that the probability of weak evidence and misleading evidence go to 0 as \( n \to \infty \). The second property implies that, when \( n \) is sufficiently large, the probability of misleading evidence of strength \( k \) is maximized at a fixed constant \( \Phi(-(2 \log k)^{1/2}) \), over all \( \theta \). Those properties ensure that with high probability we will get evidence in favor of the true value and that the probability of strong evidence in favor of a false value is
In some situations, the working model for the data can be wrong. Royall and Tsou (2003) show that under certain conditions, the likelihood ratio constructed from the working model, with a robust adjustment factor, can continue to be a valid measure for evidential interpretation. The first condition in order to use this likelihood ratio as a valid evidence function is to check whether the object of inference is equal to the object of interest for the chosen working model. We describe these concepts below.

Suppose we have \( \{f(.; \theta), \theta \in \Theta\} \) where \( \theta \) is fixed dimensional, as the working model, and there exist a true density \( g \). The Kullback-Liebler divergence between \( g \) and \( f \) is \( K(g : f) = E_g\{\log g(. ) - \log f(. ; \theta)\} \). Let \( \theta_g \) be the value of \( \theta \) that maximizes \( E_g\{\log f(. ; \theta)\} \); that is, \( \theta_g \) minimizes the Kullback-Liebler divergence between \( f \) and \( g \). Then it can be shown that the likelihood ratio \( L(\theta_g)/L(\theta) \) constructed from \( f \) converges to infinity with probability 1. This tells us that the likelihood under the wrong model represents evidence about \( \theta_g \). Suppose we are interested in \( E_g(Y) \). \( \theta_g \) and \( E_g(Y) \) are referred as the object of inference and the object of interest in Royall and Tsou (2003). If our working model is wrong, then \( \theta_g \) might not be equal to \( E_g(Y) \), and the likelihood ratio will favour the wrong value \( \theta_g \) over the true value \( E_g(Y) \) since \( P_g(L(\theta_g)/L(E_g(Y) \to \infty) = 1 \). Thus, we essentially need to understand what \( \theta_g \) represents in our working model \( f \), and specifically, check if \( \theta_g \) corresponds to \( E_g(Y) \) once \( f \) is chosen. This can be done analytically (Royall and Tsou, 2003) or through simulations (Section 3).

To allow for pure likelihood interpretation here we propose using composite likelihood ratios for genetic association studies when we have binary data with correlated outcomes. Our method provides full likelihood interpretation for the inference, i.e. support intervals, odds ratio (OR) interpretation, shape of the function and ability to compare the relative evidence for all parameter values. It is easy to implement and flexible to incorporate any data structure including independent controls.
2 Methods

2.1 Composite Likelihoods: Definitions and Notations

Composite likelihoods are constructed by multiplying together lower dimensional likelihood objects (Lindsay, 1988). They are useful for inference when the full likelihood is intractable or impractical to construct. Suppose \( Y = (Y_1, Y_2, \ldots, Y_m) \) is an \( m \)-dimensional random variable with a specified joint density function, \( f(y; \theta) \), where \( \theta \in \Theta \subset \mathbb{R}^d \) is some unknown parameter. Considering this parametric model and a set of measurable events \( \{A_k; i = 1, \ldots, K\} \), a composite likelihood is defined as

\[
CL(\theta; y) = \prod_{k=1}^K f(y \in A_k; \theta)^{w_k},
\]

where \( w_k, k = 1, \ldots, K \) are positive weights. The associated composite log-likelihood is denoted by

\[
cl(\theta; y) = \log CL(\theta; y)
\]

following the notation in Varin (2008). When we consider a random sample of size \( n \), the composite likelihood becomes

\[
CL(\theta; y) = CL(\theta) = \prod_{i=1}^n CL(\theta; y_i) = \prod_{i=1}^n \prod_{k=1}^K f(y_i \in A_k; \theta)^{w_k}
\]

with the composite score function \( u(\theta; y) = u(\theta) = \Delta_\theta cl(\theta) \), where \( \Delta_\theta \) is the differentiation operation with respect to the parameter \( \theta \). In the following, we drop the argument \( y \) for notational simplicity.

Note that the parametric statistical model \( \{f(y; \theta), y \in \mathcal{Y} \subset \mathbb{R}^m, \theta \in \Theta \subset \mathbb{R}^d\} \) may or may not contain the true density \( g(y) \) of \( Y \). Varin and Vidoni (2005) defined the Composite Kullback-Leibler divergence between the assumed model \( f \) and the true model \( g \) as

\[
K(g : f; \theta) = \sum_{k=1}^K E_g \{ \log g(Y \in A_k) - \log f(Y \in A_k; \theta) \} w_k.
\]

This is a linear combination of the Kullback-Leibler divergence associated with individual components of the composite likelihood. In the case where \( f(y \in A_k; \theta) \neq g_k(y) \) for some \( k \), the estimating equation \( u(\theta) = 0 \) is not unbiased, i.e. \( E_g \{ u(\theta) \} \neq 0 \ \forall \theta \). However, for the parameter value \( \theta_g \), which uniquely minimizes the composite Kullback-Leibler divergence, \( E_g \{ u(\theta_g) \} = 0 \) holds. Then, under some regularity conditions, the maximum composite likelihood estimator (MCLE), \( \hat{\theta}_{CL} = \arg \max CL(\theta) \), converges to this pseudo-true value \( \theta_g \). Note that \( \theta_g \) depends on the choice of \( A_k \). Xu (2012) provided a rigorous proof of the \( \theta_g \)-consistency of \( \hat{\theta}_{CL} \) under model misspecification. Furthermore, when \( f(y \in A_k; \theta_0) = g_k(y) \) for all \( k \), \( \hat{\theta}_{CL} \) is a consistent estimator of the true parameter value \( \theta_0 \) (Xu, 2012).

In many practical settings, the parameter of interest is only a subset of the parameter space. In such cases, we partition \( \theta \) into \( \theta = (\psi, \lambda) \in \Theta \subset \mathbb{R}^d \), where \( \psi \in \mathbb{R}^p \) is
the parameter of interest and $\lambda \in \mathbb{R}^q$ is the nuisance parameter, with $p + q = d$. Then, $\hat{\theta}_\psi = (\psi, \hat{\lambda}(\psi))$ denotes the constrained MCLE of $\theta$ for fixed $\psi$, and $CL_p(\psi)$ is the profile composite likelihood function, $CL_p(\psi) = CL(\hat{\theta}_\psi) = \max_\lambda CL(\psi, \lambda)$. The composite score function is partitioned as $u(\theta) = [u_\psi(\theta) \quad u_\lambda(\theta)]^t = [\partial cl(\theta)/\partial \psi \quad \partial cl(\theta)/\partial \lambda]^t$. Taking the expectation of its second moments, we obtain the variability matrix,

$$J = \begin{bmatrix} J_{\psi \psi} & J_{\psi \lambda} \\ J_{\lambda \psi} & J_{\lambda \lambda} \end{bmatrix},$$

with $J_{\psi \psi} = E \{ (\partial cl(\theta; Y)/\partial \psi)^2 \}$ and $J_{\psi \lambda} = E \{ (\partial cl(\theta; Y)/\partial \psi) (\partial cl(\theta)/\partial \lambda) \}$. The information in the composite score function is given by $G(\theta) = H(\theta)J(\theta)^{-1}H(\theta)$ where $H$ is the sensitivity matrix defined along with its inverse.

$$H = \begin{bmatrix} H_{\psi \psi} & H_{\psi \lambda} \\ H_{\lambda \psi} & H_{\lambda \lambda} \end{bmatrix}, \quad H^{-1} = \begin{bmatrix} H_{\psi \psi} & H_{\psi \lambda} \\ H_{\lambda \psi} & H_{\lambda \lambda} \end{bmatrix},$$

with $H_{\psi \psi} = E \{ -\partial^2 cl(\theta; Y)/\partial \psi^2 \}$ and $H_{\psi \lambda} = E \{ -\partial^2 cl(\theta; Y)/\partial \psi \partial \lambda \}$.

### 2.2 Composite likelihood inference in the likelihood paradigm

We propose that the composite likelihood and its corresponding set of all possible likelihood ratios can be used as a surrogate for the real likelihood ratios to provide pure likelihood inference for a given date set. For this, we need to prove that the composite likelihood functions have the two crucial performance properties possessed by real likelihood functions and some pseudo likelihoods (Section 1.1). Since composite likelihoods can be seen as misspecified likelihoods, we need to derive the robust adjustment factor defined in Royall and Tsou (2003), so that the inference becomes robust against model misspecification. As a first condition, we need to determine whether the object of inference is equal to the object of interest, which can only be checked after the working model $f$ is chosen.

In Theorem 1, we show that composite likelihood functions, with the robust adjustment factor, have the two important performance properties of the likelihood paradigm (Royall and Tsou, 2003).

**Theorem 1.** Assume $Y = (Y_1, Y_2, ..., Y_m)$ is a random vector from an unknown dis-
distribution \( g(y) \). The parametric model \( f(\theta; y) \) is chosen as the working model, with \( \theta \in \Theta \subset \mathbb{R} \). Let \( \theta_g \) be the (unique) minimizer of the composite Kullback-Leibler divergence between \( f \) and \( g \). Assume \( Y_1, ..., Y_n \) is \( n \) independent and identically distributed observations from the model \( g(.) \). Under regularity conditions on the component log densities in Appendix A of the supplementary material, the following properties hold: (a) For any value \( \theta \neq \theta_g \), the evidence will eventually support \( \theta_g \) over \( \theta \) by an arbitrarily large factor; \( P_g(CL(\theta_g)/CL(\theta) \to \infty \text{ as } n \to \infty) = 1 \). (b) In large samples, the probability of misleading evidence, as a function of \( \theta \), is approximated by the bump function, \( P_g((CL(\theta)/CL(\theta_g))^{a/b} \geq k) \to \Phi(-c/2 - \log(k)/c) \), where \( k > 1 \), \( \Phi \) is the standard normal distribution function, \( c \) is proportional to the distance between \( \theta \) and \( \theta_g \), \( a = E_g\{\Delta \theta u(\theta_g; Y)\} \) and \( b = \text{Var}_g\{u(\theta_g; Y)\} \). The results can be extended to the case where \( \theta \) is a fixed dimensional vector parameter. The proof is in Appendix A of the supplementary material. Note that we can substitute the \( a \) and \( b \) terms with the consistent estimates \( \hat{a} = n^{-1}\sum_{i=1}^{n}u(\hat{\theta}_{CL}; Y_i) \) and \( \hat{b} = n^{-1}\sum_{i=1}^{n}(u(\hat{\theta}_{CL}; Y_i))^2 \), where \( \hat{\theta}_{CL} \) is the MCLE.

Suppose \( \theta \in \Theta \subset \mathbb{R}^d \) is partitioned as \( \theta = (\psi, \lambda) \) and \( \psi \) is a parameter of interest. It was shown in Royall (2000) that the large-sample bound for the probability of misleading evidence, \( \Phi(-2\log(k)^{1/2}) \) holds for profile likelihoods. In Theorem 2, we show that the profile composite likelihood also has these two properties.

**Theorem 2.** Assume \( Y = (Y_1, Y_2, ..., Y_m) \) is a random variable from an unknown distribution \( g(y) \), the model \( f(\theta; y) \) is the assumed model, with \( \theta \in \Theta \subset \mathbb{R}^2 \) partitioned as \( \theta = (\psi, \lambda) \) and \( \psi \) is a parameter of interest. Let \( Y_1, ..., Y_n \) be \( n \) independent and identically distributed observations from the model \( g(.) \). Under regularity conditions on the component log densities in Appendix A of the supplementary material, the following properties hold.

(a) For any false value \( \psi \neq \psi_g \), the evidence will eventually support \( \psi_g \) over \( \psi \) by an arbitrarily large factor;

\[
\frac{CL_p(\psi_g)}{CL_p(\psi)} \to^p \infty \quad n \to \infty \tag{1}
\]

(b) In large samples, the probability of misleading evidence, as a function of \( \psi \), is
approximated by the bump function,

$$P_g \left\{ \left( \frac{CL_p(\psi)}{CL_p(\psi_g)} \right)^{a/b} \geq k \right\} \to \Phi \left( -\frac{c^*}{2} - \frac{\log(k)}{c^*} \right) \quad (2)$$

where $k > 1$, $\Phi$ is the standard normal distribution function, $c^* = ca/b^{1/2}$, $c$ is proportional to the distance between $\psi$ and $\psi_g$, $a = H^{\psi \psi}(\psi_g, \lambda_g)^{-1}$ and $b = H^{\psi \psi}(\psi_g, \lambda_g)^{-1}G^{\psi \psi}(\psi_g, \lambda_g)H^{\psi \psi}(\psi_g, \lambda_g)^{-1}$.

**Proof.** See Appendix A of the supplementary material.

The results can be extended to the case where $\psi$ and $\lambda$ are fixed dimensional vector parameters. Again, we substitute the $a$ and $b$ terms with consistent estimates. Note that the adjustment factor $a/b$ simplifies to $H^{\psi \psi}/G^{\psi \psi}$ since we assume $\psi$ is a scalar. This ratio is equal to the adjustment factor proposed by Pace et al. (2011) in order to get a composite likelihood ratio test converging to a $\chi^2$ distribution instead of converging to $\sum \nu_i \chi^2_{i}$, where the $\nu_i$’s are the eigenvalues of the matrix $(H^{\psi \psi})^{-1}G^{\psi \psi}$.

### 2.3 Modelling correlated binary data using composite likelihoods

Consider a genetic association study where there are $N$ independent families with $n_i$ observations in the $i^{th}$ family, $i = 1, \ldots, N$. Let $Y_i = (Y_{i1}, \ldots, Y_{in_i})$ be a binary response for the $i^{th}$ family, where $Y_{ij}$ indicates whether the individual $j$ in the $i^{th}$ family has the trait or not ($Y_{ij} = 1$ or $0$, respectively). Similarly the genotype data vector at a particular SNP is defined as $X_i = (X_{i1}, \ldots, X_{in_i})$, where the SNP genotypes, $X \in \{0, 1, 2\}$, represent the number of minor alleles for a given SNP. We look at the relative evidence for different values of the ORs for SNPs genome-wide or in a candidate region.

In general, constructing a fully specified probabilistic model for correlated binary data is challenging. A joint probability mass function (pmf) for correlated binary variables was first proposed by Bahadur (1961), which involves writing the joint probabilities as functions of marginal probabilities and second and higher order correlations. Although the Bahadur representation provides a tractable expression of a pmf, it has some limitations (Bahadur (1961), Molenberghs and Verbeke (2005, chap.
7). Other approaches for modelling the joint pmf for correlated binary data include constructing multivariate probit models or Dale models (Molenberghs and Verbeke, 2005). However, these are computationally intensive and hence intractable in high dimensional data.

Since evaluating the full likelihood is complicated, we construct a composite likelihood to model pedigree data and use the ratio of the composite likelihoods as our evidence function. We showed in Section 2.2 that composite likelihood can be used as a surrogate for the real likelihood function for pure likelihood analysis and evidential interpretation assuming the object of interest and object of inference are the same.

The simplest composite likelihood to construct is from independent margins and is useful if one is interested only in marginal parameters (Varin et al., 2011). Here, we are interested in the marginal parameter $\beta_1$ which is a 1st order parameter. Thus, we choose a composite likelihood constructed from lower dimensional margins using the working independence assumption since they are easier to construct and they can be more robust to model misspecifications (Jin (2010), Xu (2012)).

Consider an underlying logistic regression model with an additive effect of the genotype on a binary response, $\log(p_{ij}/(1 - p_{ij})) = \beta_0 + \beta_1 x_{ij}$, where $p_{ij} = P(Y_{ij} = 1|x_{ij}) = E(Y_{ij}|x_{ij})$ is the marginal probability that the individual $j$ in the $i^{th}$ family has the disease trait given $x_{ij} = 0, 1$ or 2. The composite likelihood constructed under the working independence assumption is $CL_{ind}(\beta_0, \beta_1) = \prod_{i=1}^{N} \prod_{j=1}^{n_i} P(Y_{ij} = y_{ij} | x_{ij}) = \prod_{i=1}^{N} \left( \prod_{j=1}^{n_i} (p_{ij})^{y_{ij}} (1 - p_{ij})^{1 - y_{ij}} \right)$, where $p_{ij} = \exp(\beta_0 + \beta_1 x_{ij})/(1 + \exp(\beta_0 + \beta_1 x_{ij})$. We can determine the profile composite likelihood $CL_p(\beta_1) = \max_{\beta_0} \{L(\beta_0, \beta_1)\}$ and compute the maximum profile composite likelihood estimate, $\hat{\beta}_{1,CL_{ind}} = \max_{\beta_1} \log CL_{ind}(\hat{\beta}_0(\beta_1), \beta_1)$. Note that we need to use the adjustment factor, $a/b$ in Eq. (2) to the composite likelihood ratio. In the next section, we use a simulation study to investigate the implications of the theoretical results in Section 2.2.
3 Simulation study

3.1 Simulation design

Consider a family with 12 members, a proportion of whom are affected (eg. Figure 2). We generate \( N = 30, 50, 100, 150, 200, 300 \) and 500 of such families with this structure to see how sample size affects the performance of our method.

![Family Diagram](image)

**Figure 2.** Example of a generated family where there are 5 affected individuals.

We keep the regression parameters constant at \( \beta_0 = -2.38 \) and \( \beta_1 = 1.76 \) throughout our simulations. With these values, the odds of disease when an individual does not carry the minor allele is 0.09 and the odds ratio is set large at 5.8. There are 5 values assumed for the dependence parameter: \( \psi_1 \) quantifies the dependence between siblings, \( \psi_2 \) quantifies the dependence between a parent and an offspring, \( \psi_3 \) corresponds to the dependence between an aunt/uncle and a niece/nephew, \( \psi_4 \) quantifies the dependence between the grandparent and the grandchild and \( \psi_5 \) quantifies the dependence between cousins. The values of the dependence parameters are chosen as \( \psi_1 = 3, \psi_2 = 2.5, \psi_3 = 2, \psi_4 = 1.5, \psi_5 = 1.2 \). We only assume positive dependence.
within pairs. See Table 1 and Appendix B of the supplementary material for the relationship between correlations within a binary pair and the odds ratio.

### Table 1. The relationship between correlations within a binary pair and odds ratio.

| odds ratio | \( \delta_{ij|(0,0)} \) | \( \delta_{ij|(0,1)} \) | \( \delta_{ij|(1,1)} \) | \( \delta_{ij|(0,2)} \) | \( \delta_{ij|(1,2)} \) | \( \delta_{ij|(2,2)} \) |
|------------|----------------|----------------|----------------|----------------|----------------|----------------|
| 1.2        | 0.015          | 0.025          | 0.042          | 0.021          | 0.037          | 0.034          |
| 3          | 0.120          | 0.155          | 0.253          | 0.099          | 0.197          | 0.222          |

where \( \delta_{ij|(k,l)} = \text{corr}(Y_i, Y_j | x_i = k, x_j = l) \) and \((Y_i, Y_j)\) is a binary pair.

Genotype data \((X)\) for families with a minor allele frequency of 0.20 are generated using SIMLA \((\text{Schmidt et al., 2005})\). To generate the 12 dimensional correlated binary vector \(Y\) given \(X\), we use the method of Emrich and Piedmonte \((1991)\). This method uses a discretised normal approach to generate correlated binary variates with specified marginal logistic probabilities and pairwise correlations given genotype \(X\). A detailed explanation of the data generation is given in Appendix B of the supplementary material.

Our main purpose is to evaluate evidence about \(\beta_1\) and determine if the procedure we propose will lead to valid inference. Our simulation must show: (1) that the maximum profile composite likelihood estimate of the parameter of interest converges to the true value as sample size increases to indicate that the object of inference is the same as the object of interest. That is, the composite likelihoods provide evidence about the true parameter (Eq.(1) of Theorem 2), and (2) The probability of observing misleading evidence is described by the bump function (Eq.(2) of Theorem 2).

For the composite likelihood constructed under the working independence assumption, we have \(\theta = (\beta_0, \beta_1)\), where \(\beta_1\) is the parameter of interest and \(\beta_0\) is the nuisance parameter. We follow the steps described in Appendix C of the supplementary material to find the maximum profile composite likelihood estimate of the parameter of interest, \(\hat{\beta}_{1CL}\). We generate 10,000 simulated data sets and estimate the parameters by averaging over 10,000 maximum profile composite likelihood estimates, \(\hat{\beta}_{1CL} = \sum_{j=1}^{10000} \hat{\beta}_{1CL}^{(j)}/10000\).

To estimate the probability of misleading evidence (Eq.(2) of Theorem 2), we first estimate the robust adjustment factor \(a/b\). Recall that \(a = H_{\psi}(\psi, \lambda_g)^{-1}\) and \(b = H_{\psi}(\psi, \lambda_g)^{-1}G_{\psi}(\psi, \lambda_g)H_{\psi}(\psi, \lambda_g)^{-1}\) where \(\psi\) is the parameter of interest,
λ is the nuisance vector. Note that for \( \theta = (\psi, \lambda) \), \( G(\theta) = H(\theta)J(\theta)^{-1}H(\theta) \) with \( H(\theta) = E_g[-\partial^2 cl(\theta; Y)/\partial \theta \partial \theta^T] \) and \( J = E_g\{(\partial cl(\theta; Y)/\partial \theta)(\partial cl(\theta; Y)/\partial \theta)^T\} \). We estimate \( J(\theta) \), using \( \hat{J}(\hat{\theta}) = 1/N \sum_{i=1}^{N} u(\hat{\theta}_{CL}, y_i)u(\hat{\theta}_{CL}, y_i)^T \), where \( u(\theta; y_i) \) are the elements of the composite score function, \( y_i \) is the observations vector, \( \hat{\theta} \) is the global MCLEs of \( \theta = (\beta_0, \beta_1) \), and \( N \) is the sample size (number of families).

Then we estimate \( H(\theta) \) by \( \hat{H}(\hat{\theta}) = \sum_{i=1}^{N} (\partial^2 cl(\theta; y_i)/\partial \theta \partial \theta^T)/N \). For the parameter of interest \( \beta_1 \), \( \hat{H}_{\beta_1\beta_1}(\hat{\theta}) \) and \( \hat{G}_{\beta_1\beta_1}(\hat{\theta}) \) are the entries of the matrices \( \hat{H}^{-1}(\hat{\theta}) \) and \( \hat{G}^{-1} \) that belong to the parameter \( \beta_1 \). Then, \( \hat{a}/\hat{b} = (\hat{H}_{\beta_1\beta_1}(\hat{\theta})^{-1})/(\hat{H}_{\beta_1\beta_1}(\hat{\theta})^{-1}\hat{G}_{\beta_1\beta_1}(\hat{\theta})\hat{H}_{\beta_1\beta_1}(\hat{\theta})^{-1}) = \hat{H}_{\beta_1\beta_1}(\hat{\theta})/\hat{G}_{\beta_1\beta_1}(\hat{\theta}) \) since \( \beta_1 \) is a scalar.

To estimate the probability of misleading evidence for each simulated dataset, calculate the proportions of the composite likelihood ratios with the robust adjustment factor that are greater than the pre-specified threshold, \( (1/10000) \sum_{j=1}^{10000} I\left\{ (CL_p(\beta_1; y^{(j)}))/CL_p(\beta_{1g}; y^{(j)}) \right\} \hat{a}/\hat{b} \geq k \), where \( y^{(j)} \) is the \( j \)th simulated dataset under the chosen model parameter \( \beta_{1g} \), \( \beta_1 \) is a parameter value that is different than \( \beta_{1g} \) and \( I \) is the indicator function.

### 3.2 Simulation results

The simulation results for determining whether the maximum profile composite likelihood estimates of \( \beta_1 \) converge to the true parameter value for sample sizes \( n = 30, 50, 100, 150, 200, 300 \) and 500 are given in Table 2. We see that as \( n \) increases, the composite likelihood approach provides consistent estimates for the true parameter value \( \beta_1 \). This ensures that the object of inference is equal to the object of interest; that is, the composite likelihood ratio is providing evidence about the true parameter of interest.

| \( n \) | 30 | 50 | 100 | 150 | 200 | 300 | 500 |
|--------|----|----|-----|-----|-----|-----|-----|
| \( \beta_{1CL_p} \) | 1.798 | 1.782 | 1.772 | 1.767 | 1.766 | 1.762 | 1.762 |

In Figure 3, we illustrate the behaviour of the probability of observing misleading
evidence for $\beta_1$ for $n = 30, 100, 300$ and 500. The solid curve indicates the probability of misleading evidence before the robust adjustment factor is applied and the dashed curve indicates this probability after the robust adjustment is applied. For illustration purposes, we chose $k = 8$. As the theoretical results predict, after robust adjustment, the probability of observing misleading evidence is approximated by the bump function with increasing sample size. The bump function has the maximum value of $\Phi(-\sqrt{2\log 8}) = 0.021$, indicated by the horizontal line in the figures.

**Figure 3.** Plots for the probability of misleading evidence before (- -) and after(–) robust adjustment for $n = 30$, $n = 100$, $n = 300$, $n = 500$ with $\beta_0 = -2.38$, $\beta_1 = 1.76$. 
In simulations where the number of individuals in families varies but only one type of relationship exists, e.g. only siblings, we looked at the performance of the likelihood ratios constructed from independent marginals and from pairwise marginals. We also considered the parameter that defines the relatedness, $\psi$, as the parameter of interest in the pairwise composite likelihood approach (Appendix D of the supplementary material). These simulations indicate that 1) both composite likelihood approaches provide valid evidence functions, 2) the composite likelihood approach from the independent marginals still performs well when there is more than one type of relatedness in the family, while the pairwise composite approach does not, 3) inference about the first order parameter $\beta_1$ is not affected by varying the value of the dependence parameter, and 4) if the parameter of interest is the second order parameter, then the pairwise likelihood approach is required to enable inference about the second order parameter (Appendix E of the supplementary material).

4 Genetic Association Analysis of Reading Disorder in Families with Rolandoic Epilepsy

Rolandoic Epilepsy (RE) is a neuro-developmental disorder characterized by centrotemporal sharp waves on EEG, focal seizures and a high frequency of comorbid speech and reading disorder (RD) in RE cases and their seizure unaffected family members. We conducted linkage analysis of RD in RE families and here we use our composite likelihood approach for analysis of genetic association at the Chromosome 1 RD linkage locus we identified in the families (Chr 1: 209,727,257-232,025,174) (Strug et al. (2012)). The data consists of 137 families and 1000 non-RD and non-RE control singletons. Some families are complex with up to 15 members. In total, there are 444 individuals in the RE families with 127 affected with RD. All have been genotyped genomewide on the Illumina Human Core Exome array. At this locus there are 2087 genotyped SNPs analyzed for association.

We constructed the composite marginal likelihood under a working independence assumption with a robust adjustment factor, to correct for the misspecified model for correlated individuals and we assumed an underlying logistic regression model with an additive model for the SNP. The composite likelihood function with the robust
adjustment factor, \( a/b \), is

\[
CL_{ind}(\beta_0, \beta_1) = \{ \prod_{i=1}^N \prod_{j=1}^{n_i} (p_{ij})^{y_{ij}} (1 - p_{ij})^{1-y_{ij}} \}^{a/b}
\]

where

\[
p_{ij} = \frac{\exp(\beta_0 + \beta_1 x_{ij})}{1 + \exp(\beta_0 + \beta_1 x_{ij})}
\]

and

\[
a/b = H^{\beta_1 \beta_1}(\beta_0, \beta_1)/G^{\beta_1 \beta_1}(\beta_0, \beta_1).
\]

Here the odds ratio (OR), \( e^{\beta_1} \) is the interest parameter, and we plot the likelihood as a function of \( e^{\beta_1} \) (Strug et al., 2010). Under the hypothesis of no association, the OR is equal to 1, and the OR is some value different from 1 under the alternative. Note that since \( \beta_0 \) is a nuisance parameter, we profile out the baseline odds, \( e^{\beta_0} \), and use the profile composite likelihood (\( CL_p \)) ratio with the robust adjustment factor as our evidence function, i.e. \( (CL_p(e^{\beta_1})/CL_p(1))^{a/b} \).

In Figure 4, we illustrate the \( CL_p \) function for the OR for three SNPs: (a) a SNP, rs1495855, displaying association evidence, (b) a SNP, rs12130212, that does not show association evidence and (c) a SNP, rs1160575, with a low cell count in the \( 2 \times 3 \) table (Table 3). By plotting the \( CL_p \) function, we can observe all the evidence about the association parameter \( e^{\beta_1} \) that the data set provides.

In Figure 4(a), the ratio of any two points on the curve represent their relative support and the theoretical and simulation results ensure this interpretation is valid. The \( 1/8 \) \( CL_p \) interval for the OR is 1.5 to 3. The OR values within this interval are consistent with the data at the level \( k=8 \), i.e. there are no other values outside this interval that are better supported than the values within the interval, by a factor of 8 (Royall, 1997). We see that OR=1 is outside of the \( 1/8 \) \( CL_p \) interval. That tells us that there are some parameter values of the OR, for example the MLE, \( \hat{OR}_{mle} = 2.1 \) and nearby values, that are better supported than an OR=1 by a factor of greater than 8. The \( 1/32 \) \( CL_p \) interval shows that an OR=1 is also not supported by the data at level \( k=32 \). The adjustment factor \( a/b \) is 0.88, which is close to 1, suggesting that the composite likelihood is not too discrepant from the true likelihood. This is due to the fact that most individuals in our data are unrelated with the 1000 singletons included in the analysis.

In Figure 4(b), we can see that both \( 1/8 \) and \( 1/32 \) \( CL_p \) intervals include OR=1 as a plausible value. This indicates us that there is no value that the data supports over OR=1 by a factor of 8 or more. In Figure 4(c), the \( CL_p \) is skewed suggesting there is sparsity in the data (see Table 3).
Table 3. Distribution of data at SNP rs1160575

| # of minor allele | disease status |  |  |  |
|-------------------|----------------|---|---|---|
| SNP               | 0              | 1160| 121 | 1281|
|                   | 1              | 153 | 6  | 159 |
|                   | 2              | 4   | 0  | 4   |
| total             |                | 1317| 127 | 1444|

Figure 4. Standardized $CL_p$ function for OR at three SNPs. $1/8$ and $1/32$ $CL_p$ intervals ($CL_p I$) as well as the estimated robust adjustment factor $\hat{a}/\hat{b}$ are provided.
In genetic association studies, one often needs to evaluate many SNPs in a region or genome-wide. Plotting hundreds of individual likelihood functions corresponding to each SNP may not be practical. Instead, a single plot that represents the association information in a region of interest can be displayed (Strug et al., 2010) and followed up by individual likelihood plots at a small number of markers of interest. Figure 5(a) presents the $CL_p$ intervals for 2087 SNPs under the Chromosome 1 linkage peak from 1444 individuals. We display the SNPs by base pair position on the x-axis and OR on the y-axis. The vertical lines for each SNP on the x-axis represent the $1/k$ $CL_p$ intervals where $k = 32$, 100 and 1000. Only the SNPs whose $1/100$ $CL_p$ intervals do not include the OR=1 as a plausible value are displayed in colour and noted as providing strong evidence for ORs different from 1 for a given $k$. The $CL_p$ intervals displayed in grey include OR=1 (horizontal line at OR=1) as a plausible value so the SNPs that produced these intervals are not concluded to display strong evidence for association. If the $1/k$ $CL_p$ interval does not include OR=1, then it will be coloured in green, red or navy blue for $k = 32$, 100 and 1000 respectively. For SNP rs1495855, the $1/k$ $CL_p$ interval for $k = 32$, 100 and 1000 do not include OR=1 as a plausible value, indicating evidence of an association between this SNP and RD at the level $k > 1000$. Note that the $1/32$ $CL_p$ interval for rs1495855 (the green portion) is the same as provided in Figure 4(a). The longest grey $CL_p$ interval at the left of the plot (marked with an x in the plot) corresponds to the SNP in Figure 4(c). Therefore, Figure 5(a) also provides information about the shape of the likelihood function for a given SNP.

The small horizontal tick on each $CL_p$ interval represents the MLE for the OR at the SNPs that were found to be associated with RD for some $k$. The max $CL_p$ ratios, calculated by $[CL_p(\hat{OR}_{mle})/CL_p(1)]^{a/b}$, for the three SNPs where the strength of evidence for association is the largest are also provided on the plot. The SNP rs1495855 provided the largest likelihood ratio with an MLE for the OR=2.1.
Figure 5. Evidential analysis of association between SNPs at chromosome 1 and RD (0 or 1) using a composite likelihood from independent margins where the margins are logistic regression models with genotypes coded additively, with a robust adjustment (a). Analysis of the data using a GEE approach with an independent correlation structure; y-axis provides log_{10} P-values (b).

Using GEE with an independent correlation structure to assess association provides results that are consistent with the composite likelihood approach. That is, all of the SNPs that provide $CL_p$ ratios for ORs that are better supported than an OR=1 by a factor of greater than 100 are among the ones that produce $P$-values <0.01 in the GEE approach. Moreover, the three SNPs that have the maximum likelihood ratios also have the smallest $P$-values in the GEE analysis, i.e. $P$-values for SNPs
rs1495855, rs12748250 and rs6697921 are < 0.000001, < 0.00001 and < 0.0001 respectively. Figure 5 compares the GEE analysis results with the evidential analysis results. In Figure 5(b), the SNPs by base pair position are displayed on the x-axis as in Figure 5(a) and the log₁₀ P-values for the corresponding SNPs from the GEE analysis are displayed on the y-axis. The smallest P-value corresponds to SNP rs1495855 and the OR estimated from the GEE analysis is 2.1. Figure 5(b) only indicates that the probability of observing a result this extreme or more is unlikely if the true OR is 1.

4.1 Multiple Hypothesis Testing Adjustments

Until now we have not considered multiple hypothesis testing. The probability of observing a LR > k at a single SNP if OR = 1 is true is bounded (Eq. (2)). But if one aims to have the probability across all SNPs bounded, there are some alternative considerations. Let H₀ be the hypothesis that none of the N SNPs are associated with the trait. To control the family-wise error rate (FWER), which is the probability of at least one LR > k among N hypotheses when H₀: OR = 1 is true, let M₀(n, N, k) be the FWER where n is the sample size and k is the criterion for the measure of evidence. Then,

\[
FWER = M₀(n, N, k) = P₀ ((LR₁ ≥ k) ∪ (LR₂ ≥ k) ∪ ... ∪ (LRₙ ≥ k)) 
\leq P₀(LR₁ ≥ k) + P₀(LR₂ ≥ k) + ... + P₀(LRN ≥ k) 
= \sum_{j=1}^{N} M₀^{(j)}(n, k)
\]

where M₀⁽(j⁾)(n, k) is the probability of observing misleading evidence at the j-th SNP for two simple hypotheses for the OR. M₀⁽(j⁾)(n, k) is a planning probability and so generally, H₀: OR = 1, and H₁ is the OR that is the minimum clinically important difference, since for larger ORs, M₀ is smaller (Strug and Hodge, 2006b).

For planning purposes M₀⁽(j⁾)(n, k) are the same for all j. Thus, a conservative upper bound on the FWER is NM₀(n, k). Since M₀(n, k) is usually very small for any given SNP, it may provide a reasonable upper bound for the FWER. Otherwise, increasing the sample size can dramatically lower the FWER (Strug and Hodge,
suggesting sample size is an adjustment for multiple hypothesis testing.

We simulated $10^5$ replicates under no association ($OR = 1$). Let $y^{(j)}$ be the $j^{th}$ simulated phenotype under $H_0$ given the corresponding genotype, $CL_p(OR; y^{(j)})$ is the profile composite likelihoods evaluated at a chosen OR, and $I$ is an indicator function. Then we evaluate the likelihood ratio for $OR = 2$ and $OR = 2.5$ versus $OR = 1$ and we estimate $M_0(n, k)$ using $\frac{1}{10^5} \sum_{j=1}^{10^5} I[\{CL_p(OR; y^{(j)})/CL_p(1; y^{(j)})\}^{a/b} \geq k]$. The effective number of independent tests in the set of 2087 dependent markers was estimated as 1413 (Li et al., 2012). Thus, $N = 1413$ is used in the calculation of the upper bound for the FWER.

We calculate the upper bound on the FWER for different choices of criterion $k$ ($k = 32, 64, 100$ and 1000). For $k = 1000$, the upper bound for the FWER is 0.3250 at $OR = 2$. This tells us that the probability of observing at least one $LR > k$ among 1413 SNPs when none of the SNPs are associated with the trait is bounded by 0.3250. A lower upper bound would be preferable, however, although we know that this is a crude upper bound and may not provide a good estimate of the true FWER, it is straightforward to estimate.

When feasible, the best approach to decrease the $M_0(n, k)$ and consequently the FWER is by increasing the sample size or equivalently, replicating the result in an independent sample. This approach also reduces the probability of weak evidence whereas increasing $k$ for a fixed $n$ increases weak evidence. To see how increasing the sample size will effect the upper bound on the FWER, we simulated a data set based on the original data structure, but where the number of families is doubled from 444 to 888. We see in Table 4 that the upper bound on the FWER is 0.1837 and is considerably lower with greater sample size, where we now have 1888 individuals, instead of 1444.

Table 4. Upper bound for FWER for $10^5$ replicates when the sample size is 1888.

| FWER $\leq N M_0(1888, k)$ | $k = 32$ | $k = 64$ | $k = 100$ | $k = 1000$ |
|---------------------------|---------|---------|---------|---------|
| $OR=2$                    | 1       | 1       | 1       | 0.1837  |
| $OR=2.5$                  | 1       | 0.6076  | 0.4098  | 0.0706  |
5 Summary

We have developed an alternative approach to the analysis of genetic association for correlated (family) data using the pure likelihood paradigm. The likelihood paradigm provides a full likelihood solution that enables more comprehensive inference than null hypothesis significance testing. Due to complex dependencies in family data, constructing a fully specified probabilistic model for a binary trait is challenging. Therefore, we considered working with composite likelihoods for modelling this type of data, which has also been considered in a frequentist context (Le Cessie and Van Houwelingen (1994), Kuk and Nott (2000), Zhao and Joe (2005), Zi (2009), He and Yi (2011)). We showed that LRs from composite likelihoods, with a robust adjustment, are valid statistical evidence functions in the likelihood paradigm. They have the two required performance properties of an evidence function, assuming the object of inference is equal to the object of interest, that enable the measurement of evidence strength by comparing likelihoods for any two values of an interest parameter. The robust adjustment on the composite likelihood is necessary even though the likelihood objects in the composite likelihood are correctly specified, since multiplying them to construct the composite likelihood does not in general lead to a probability density function.

If one is interested in marginal parameters (e.g. $OR = e^{\beta_1}$), we proposed constructing composite likelihoods from independent marginals when we have complex family structures. (Working with these independent likelihoods reduces the computations considerably.) Using simulation, we also examined the use of composite likelihoods for a logistic regression model with an additive effect on the marginal binary response, and we show that this choice of composite likelihood offers reliable inference as well. The composite likelihood approach contributes additional information by providing a full likelihood solution that can complement frequentist GEE analysis, and is more feasible to implement over generalized mixed models.

We applied the composite likelihood method to the analysis of genetic association on Chromosome 1 at the RD linkage locus in RE families. We found that rs1495855 provided large likelihood ratios for ORs near 2 versus OR=1. We observed an MLE of OR=2.1 and almost 24000 times greater evidence for OR near 2 versus OR=1. The $1/1000$ likelihood interval is $(1.16, 3.89)$ (not shown on Figure 5(a)). Even the values around 1.2 are better supported over OR=1 by a factor of 1000. GEE analysis also
supported evidence for association at this variant. Lastly, we discussed how FWER control is achieved in the context of this paradigm, and showed that indeed the probability of observing a misleading result across the 2089 SNPs at even $k > 1000$ was actually quite high and a replication sample would be needed to decrease the FWER.

A limitation of this approach is that it may not be optimal in small samples since the performance properties for incorrect models (e.g. composite likelihoods) rely on large sample results. Future work will determine an efficient solution for small sample adjustments, potentially using a Jacknife variance estimate as was done in small sample correction methods for GEE (Paik (1988), Lipsitz et al. (1990)). Another challenge is when interest lies in higher order parameters, like the correlation parameter. In this case, composite likelihoods that are composed of more complex marginals are required for pure likelihood inference. This makes the computations more difficult and leads to longer computational time. Finding a working model where the object of interest is equal to the object of inference may also be challenging, which is critical when working with incorrect models in any paradigm.

In conclusion, we have provided a composite likelihood approach for the analysis of genetic association in family data using the likelihood paradigm. Our method is practical, efficient and easy to implement and provides a reliable evidence function when the real likelihoods are intractable or impractical to construct.

Supplemental Material

A  Proofs of Theorem 1 and Theorem 2

A.1 Regularity Conditions

The regularity conditions (A1-A6) are provided in (Knight, 2000, p.245). Let \( l(\theta; y) = \log f(y; \theta) \) and let \( l_\theta(\theta; y), l_{\theta\theta}(\theta; y) \) and \( l_{\theta\theta\theta}(\theta; y) \) be the first three partial derivatives of \( l(\theta; y) \) with respect to \( \theta \). These conditions apply on the component log densities of a composite likelihood.

A1. The parameter space \( \Theta \) is an open subset of the real line.

A2. The set \( A = \{ y : f(x; \theta) > 0 \} \) does not depend on \( \theta \).

A3. \( f(y; \theta) \) is three times continuously differentiable with respect to \( \theta \) for all \( y \) in \( A \).

A4. \( E[l_\theta(\theta; y)] = 0 \) for all \( \theta \) and \( \text{Var}[l_\theta(\theta; y)] = I(\theta) \) where \( 0 < I(\theta) < \infty \) for all \( \theta \).

A5. \( E[l_{\theta\theta}(\theta; y)] = -J(\theta) \) where \( 0 < J(\theta) < \infty \) for all \( \theta \).

A6. For each \( \theta \) and \( \delta > 0 \), \( |l_{\theta\theta\theta}(t; y)| \leq M|x| \) for \( |\theta - t| \leq \delta \) where \( E_\theta[M(Y_i)] < \infty \)

A7. There exists a unique point \( \theta_g \in \Theta \) which minimizes the composite Kullback-Lebler divergence in Eq. 3 (Xu, 2012).

\[
K(g : f; \theta) = \sum_{k=1}^{K} E_g[\log g(Y \in A_k) - \log f(Y \in A_k; \theta)] w_k. \tag{3}
\]

Condition A4 changes when there is model misspecification (e.g. setting up wrong marginal or conditional densities in composite likelihoods), e.g. \( E_g[l_\theta(\theta; y)] = 0 \) only for \( \theta = \theta_g \), where the expectation is taken under the correct (unknown) model \( g \).

It can be deduced that the mean and variance of the log likelihood derivatives, \( l_\theta(\theta; y), l_{\theta\theta}(\theta; y) \) and \( l_{\theta\theta\theta}(\theta; y) \) are of order \( O(n) \). The higher order derivatives are, in general, of order \( O_p(n) \) (Severini, 2000, p.88).

According to Severini (2000, p.106), sufficient conditions for the consistency of the MLE for regular models are:
1. Θ is a compact subset of \( \mathbb{R}^d \).

2. \( \sup_{\theta \in \Theta} |n^{-1}l(\theta) - n^{-1}E\{l(\theta)\}| \to^p 0 \) as \( n \to \infty \).

We need the second condition to hold on the component log densities. Let \( l_i \) be the \( i^{th} \) component log density in the composite likelihood with \( i = 1, \ldots, d \), such that \( cl(\theta) = \sum_{i=1}^{d} n^{-1}l_i(\theta) \) then

\[
\left| \sum_{i=1}^{d} n^{-1}l_i(\theta) - \sum_{i=1}^{d} n^{-1}E\{l_i(\theta)\} \right| \leq \sum_{i=1}^{d} |n^{-1}l_i(\theta) - n^{-1}E\{l_i(\theta)\}|
\]

\[
\sup_{\theta \in \Theta} \left| \sum_{i=1}^{d} n^{-1}l_i(\theta) - \sum_{i=1}^{d} n^{-1}E\{l_i(\theta)\} \right| \leq \sup_{\theta \in \Theta} \sum_{i=1}^{d} |n^{-1}l_i(\theta) - n^{-1}E\{l_i(\theta)\}|
\]

\[
= \sum_{i=1}^{d} \sup_{\theta \in \Theta} |n^{-1}l_i(\theta) - n^{-1}E\{l_i(\theta)\}| \quad (4)
\]

If each component in Eq.(4) goes to 0 in probability, then the term on the left side goes to 0 in probability. Furthermore, see (Xu, 2012) for a more detailed regularity conditions that are needed for the consistency of the maximum composite likelihood estimator.

### A.2 Proof of Theorem 1

(a) We want to show \( P_g\{\text{CL}(\theta_g)/\text{CL}(\theta) \to \infty \text{ as } n \to \infty \} = 1 \). The composite likelihood function for \( n \) observations is \( \text{CL}(\theta) = \Pi_{i=1}^{n} \text{CL}(\theta; y_i) \). Let \( R_n = \Pi_{i=1}^{n} \text{CL}(\theta_g; y_i)/\Pi_{i=1}^{n} \text{CL}(\theta; y_i) \). We want \( R_n \to \infty \).
Let \( cl(\theta; y) = \log CL(\theta; y) \).

\[
\log \left( \frac{\prod_{i=1}^{n} CL(\theta_g; y_i)}{\prod_{i=1}^{n} CL(\theta; y_i)} \right)^{1/n} = \frac{1}{n} \left( \sum_{i=1}^{n} cl(\theta_g; y_i) - \sum_{i=1}^{n} cl(\theta; y_i) \right) \\
= \frac{1}{n} \left( \sum_{k=1}^{K} w_k \left\{ \sum_{i=1}^{n} \log(f(y_i \in A_k; \theta_g)) - \sum_{i=1}^{n} \log(f(y_i \in A_k; \theta)) \right\} \right) \\
\rightarrow a.s \quad \sum_{k=1}^{K} w_k \left\{ \beta_g \left[ \log(f(Y \in A_k; \theta_g)) - \log(f(Y \in A_k; \theta)) \right] \right\} \quad (5)
\]

> 0

since \( w_k \)'s are positive and \( \theta_g \) minimizes the \( K(g : f; \theta) \). (5) is true by the Strong Law of Large Numbers. Since \((1/n) \log R_n \rightarrow c > 0\), where \( c \) is a finite positive number, then \( R_n = \frac{\prod_{i=1}^{n} CL(\theta_g; y_i)}{\prod_{i=1}^{n} CL(\theta; y_i)} \rightarrow \infty \)

(b) We want \( P_g\{[CL(\theta)/CL(\theta_g)]^{a/b} \geq k}\} \rightarrow \Phi(-c/2 - \log(k)/c) \) where \( c \) is proportional to the distance between \( \theta \) and \( \theta_g \). Note that \( CL(\theta; y) = \Pi_{k=1}^{K} f(y \in A_k; \theta)^{\omega_k} \) and \( cl(\theta; y) = \log CL(\theta; y) = \sum_{k=1}^{K} \omega_k \log f(y \in A_k; \theta) \).

Composite score function: \( u(\theta; y) = \nabla_\theta cl(\theta; y) = \sum_{k=1}^{K} \omega_j \nabla \log f(y \in A_k; \theta) \)

The sensitivity matrix under the correct model:

\[
H(\theta) = \mathbb{E}_g (-\nabla_\theta u(\theta; Y)) = \int -\nabla_\theta u(\theta; y) g(y) dy
\]

The variability matrix under the correct model:

\[
J(\theta) = \text{var}_g(u(\theta; Y))
\]

The Godambe information matrix (Godambe, 1960) under the correct model is

\[
G(\theta) = H(\theta)J(\theta)^{-1}H(\theta).
\]
Then for \( n \) independent and identically distributed observations \( Y_1, \ldots, Y_n \) from the model \( g(\cdot) \), as \( n \to \infty \), under the regularity conditions, we have;

\[
\sum_{i=1}^{n} \frac{u(\theta_g; y_i)}{\sqrt{n}} \rightarrow^d N \left( 0, J(\theta_g) \right) \quad \text{since } E_g(u(\theta_g; Y)) = 0 \quad (6)
\]

\[
\sum_{i=1}^{n} \frac{\nabla_{\theta} u(\theta_g; y_i)}{n} \rightarrow -H(\theta_g) \quad (7)
\]

where \( \theta_g \) is the (unique) minimizer of the composite Kullback-Leibler divergence between \( f \) and \( g \). Let \( \theta = \theta_g + c/\sqrt{n} \), then the Taylor expansion of the log composite likelihood around \( \theta_g \) is;

\[
cl(\theta) - cl(\theta_g) = u(\theta_g)(\theta - \theta_g) + \nabla_{\theta} u(\theta_g) \frac{(\theta - \theta_g)^2}{2} + O_p(n^{-1/2})
\]

\[
= \sum_{i=1}^{n} u(\theta_g; y_i) \frac{c}{\sqrt{n}} + \sum_{i=1}^{n} \nabla_{\theta} u(\theta_g; y_i) \frac{c^2}{2n} + O_p(n^{-1/2})
\]

\[
\rightarrow^d N \left( \frac{c^2}{2} \frac{\mathbb{E}(\nabla_{\theta} u(\theta_g; Y))}{a=\text{H}(\theta_g)}, \frac{c^2 \text{var}(u(\theta_g; Y))}{b=J(\theta_g)} \right) \quad \text{(from Eq. (6) and (7))}
\]

\[
\rightarrow N \left( -\frac{c^2}{2} a, c^2 b \right) \quad (8)
\]

\( O_p(n^{-1/2}) \) can be justified since the log composite likelihood is a finite sum of genuine log likelihoods, which are of the same order. Note that Eq.(8) does not generate the bump function since the mean is not the negative half of the variance in the asymptotic normal distribution. In order to obtain the bump function, we can adjust the ratio of composite likelihoods by raising it to the power \( (a/b) \);
\[
\frac{a}{b} \log \frac{CL(\theta; y)}{CL(\theta_g; y)} \to N \left( -\frac{a^2c^2}{2b}, -\frac{a^2c^2}{b} \right)
\]  

(9)

\[
\therefore \lim_{n \to \infty} P \left( \left( \frac{CL(\theta; y)}{CL(\theta_g; y)} \right)^{a/b} \geq k \right) = \Phi \left( -\frac{c^* - \log k}{c^*} \right)
\]

where \( c^* = \frac{ac}{\sqrt{b}} \)

We can estimate \( a/b \) through consistent estimates of \( J(\theta) \) and \( H(\theta) \). Let \( \hat{\theta}_{CL} \) be the maximum likelihood estimator of \( \theta \), which is a consistent estimator of \( \theta_g \) (Xu, 2012) then

\[
\hat{a} = \frac{1}{n} \sum_{i=1}^{n} \nabla_{\theta}u(\hat{\theta}_{CL}; y_i)
\]

\[
\hat{b} = \frac{1}{n} \sum_{i=1}^{n} u^2(\hat{\theta}_{CL}; y_i)
\]

A.3 Proof of Theorem 2

(a) We want to show,

\[
\frac{CL_p(\psi_g; y)}{CL_p(\psi, y)} \to^p \infty \quad n \to \infty
\]  

(10)

\( CL_p(\psi_g; y) = CL(\psi_g, \hat{\lambda}(\psi_g); y) = \sup_{\lambda} CL(\psi_g, \lambda; y) \geq CL(\psi_g, \lambda; y) \quad \forall \lambda \) thus true for \( \lambda_g \).

Then it would be enough to show \( \frac{CL(\psi, \lambda; y)}{CL_p(\psi, y)} \to^p \infty \) since \( \frac{CL_p(\psi_g; y)}{CL_p(\psi; y)} \geq \frac{CL(\psi_g, \lambda_g, y)}{CL(\psi, \lambda; y)} \). This will imply that Eq.(10) holds.

In Severini (2000) on page 127, it was shown that the difference between a profile log-likelihood function from a genuine log likelihood function is of order \( O_p(1) \), i.e. \( l_p(\psi; y) = l(\psi, \lambda(\psi); y) + O_p(1) \), here \( l(\psi, \lambda(\psi); y) \) refers to a genuine log likelihood function as it can be obtained from an actual model for the data using a Taylor expansion \( l_p(\psi; y) = l(\psi, \hat{\lambda}(\psi); y) \) about \( l(\psi, \lambda(\psi); y) \). Following
a similar Taylor expansion for the composite likelihood, we get;

\[
cl(\psi, \hat{\lambda}(\psi)) = cl(\psi, \lambda(\psi)) + cl(\psi, \lambda(\psi)) \langle \hat{\lambda}(\psi) - \lambda(\psi) \rangle
\]

\[
+ \frac{1}{2} (\hat{\lambda}(\psi) - \lambda(\psi))^T cl(\psi, \lambda(\psi)) (\hat{\lambda}(\psi) - \lambda(\psi)) + ...
\]

Then if \( \hat{\lambda}(\psi) = \lambda(\psi) + O_p(n^{1/2}) \) is true then we conclude that \( cl_p(\psi; y) = cl(\psi, \lambda(\psi)) + O_p(1) \). Since \( cl(\psi, \lambda(\psi)) \) is a finite sum of genuine log-likelihood functions, under regularity condition on genuine likelihood functions, \( cl(\psi, \lambda(\psi)) = O_p(\sqrt{n}) \) and \( cl(\lambda(\psi, \lambda(\psi)) = O_p(n) \).

Why is \( \hat{\lambda}(\psi) = \lambda(\psi) + O_p(n^{1/2}) \) true?

Remember \( \theta_g = (\psi_g, \lambda_g) \) is the value of the parameter that minimizes the K-L divergence between the assumed model \( f \) and the true model \( g \). In the profile composite likelihood \( CL(\psi) = CL(\psi, \hat{\lambda}(\psi)) = \sup \lambda CL(\psi, \lambda) \), \( \hat{\lambda}_\psi \) is the maximum likelihood estimate of \( \lambda \) for a fixed \( \psi \). In general \( \hat{\lambda}(\psi) \) is not a consistent estimator of \( \lambda_g \) unless \( \psi \) is fixed at the ‘true’ value, \( \psi_g \). Note that:

\[
\frac{1}{n} cl(\psi, \lambda) - \frac{1}{n} E_g[cl(\psi, \lambda)] \xrightarrow{P} 0.
\]

Following the arguments in Severini (2000), section 4.2.1, the maximizer of \( cl(\psi, \lambda)/n \) should converge in probability to the maximizer of \( E_g[cl(\psi, \lambda)]/n \), which is \( (\psi_g, \lambda_g) \). It was shown in Xu (2012) that the maximum composite likelihood estimator, \( \hat{\theta}_{CL} \), converges almost surely to \( \theta_g \) where \( \theta_g \) is the parameter that minimizes the Kullback-Leibler divergence between the working model \( f \) and the true model \( g \) (Eq. (3)). Here, we treat \( \psi \) fixed, then \( \lambda(\psi) \) becomes the only parameter and \( \hat{\lambda}(\psi) \) is the MLE of \( \lambda(\psi) \) for a fixed \( \psi \). Note that when \( \psi = \psi_g \), \( \lambda(\psi_g) = \lambda_g \). By following the regular arguments about the composite MLEs in Xu (2012), it can be shown that \( \hat{\lambda}(\psi) \rightarrow \lambda(\psi) \) as \( n \rightarrow 0 \), where \( \lambda(\psi) \) is the value of \( \lambda \) that maximizes \( n^{-1} E_g[l(\psi, \lambda)] \) when \( \psi \) is fixed. The asymptotic distribution of \( \sqrt{n} \left( \hat{\lambda}(\psi) - \lambda(\psi) \right) \) is derived in Eq.(17) and Eq.(20). Thus \( \hat{\lambda}(\psi) = \lambda(\psi) + O_p(n^{-1/2}) \) and \( cl_p(\psi) = cl(\psi, \lambda(\psi)) + O_p(1) \).
It follows that:

$$(1/n) \log \frac{CL(\psi_g, \lambda_g)}{CL_p(\psi)} = (1/n)(cl(\psi_g, \lambda_g) - cl(\psi, \lambda(\psi))) + (1/n)O_p(1) \quad (11)$$

where $cl(\theta) = \log CL(\theta)$.

$$\log \left( \frac{\Pi_{i=1}^n CL(\psi_g, \lambda_g; y_i)}{\Pi_{i=1}^n CL(\psi, \lambda(\psi); y_i)} \right)^{1/n} = \frac{1}{n} \left( \sum_{i=1}^n cl(\psi_g, \lambda_g; y_i) - \sum_{i=1}^n cl(\psi, \lambda(\psi); y_i) \right) + (1/n)O_p(1)$$

$$= \frac{1}{n} \left( \sum_{k=1}^K w_k \left\{ \sum_{i=1}^n \log(f(y_i \in A_k; \psi_g, \lambda_g)) \right. \right. \\
\left. \left. - \sum_{i=1}^n \log(f(y_i \in A_k; \psi, \lambda(\psi))) \right\} \right) + (1/n)O_p(1)$$

$$\overset{p}{\rightarrow} \sum_{k=1}^K w_k \left\{ E_g \left[ \log(f(Y \in A_k; \psi_g, \lambda_g)) - \log(f(Y \in A_k; \psi, \lambda(\psi))) \right] \right\} > 0$$

since $w_k$’s are positive and $\theta_g = (\psi_g, \lambda_g)$ minimizes the Kullback-Leibler divergence in (3).

Let $R_n = \Pi_{i=1}^n CL(\psi_g, \lambda_g; y_i)/\Pi_{i=1}^n CL(\psi, \lambda(\psi); y_i)$. We get $1/n \log R_n \to c > 0$, where $c$ is a finite positive number, then $R_n = \Pi_{i=1}^n CL(\psi_g, \lambda_g; y_i)/\Pi_{i=1}^n CL(\psi, \lambda(\psi); y_i) \overset{p}{\to} \infty$. \hfill \Box

(b) We want to show $\lim_{n \to \infty} P_g \left( \frac{CL_p(\psi)}{CL_p(\psi_g)} \geq k \right) = \Phi \left( -\frac{c}{2} - \frac{\log k}{c} \right)$, where $c$ is proportional to the distance between $\psi$ and $\psi_g$.

Following the proof of Royall (2000) for profile likelihoods: Let $cl_p(\psi) = \log CL_p(\psi)$.

For $\psi = \psi_g + c/\sqrt{n}$,

$$cl_p(\psi) - cl_p(\psi_g) = cA_n + (c^2/2)B_n + R_n \quad (12)$$

where $A_n = \frac{1}{\sqrt{n}} \left. \frac{dcl_p(\psi)}{d\psi} \right|_{\psi_g}$, $B_n = \frac{1}{n} \left. \frac{d^2cl_p(\psi)}{d\psi^2} \right|_{\psi_g}$ and $R_n = O_p(n^{-1/2})$.
We make a Taylor expansion of \( \frac{\partial \text{cl}(\psi, \lambda)}{\partial \psi} \) about \( \frac{\partial \text{cl}(\psi, \lambda)}{\partial \psi} \) as follows:

\[
\frac{\partial \text{cl}(\psi, \hat{\lambda}(\psi))}{\partial \psi} = \frac{\partial \text{cl}(\psi, \lambda)}{\partial \psi} \bigg|_{(\psi, \hat{\lambda}(\psi))} + \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi, \lambda_g)} (\hat{\lambda}(\psi) - \lambda_g) + R^*_n
\]

We observe that \( \lambda(\psi_g) = \lambda_g \) and that \( \text{cl}(\psi, \lambda(\psi)) \) is a finite sum of genuine log-likelihood functions. Then \( R^*_n \) in Eq.(15) is of \( O_p(1) \) since the higher order derivatives of log-likelihood function are of order \( O_p(n) \) and \( (\hat{\lambda}(\psi_g) - \lambda_g) = O_p(n^{-1/2}) \) due to Eq.(20).

Then (13) becomes:

\[
\frac{1}{\sqrt{n}} \frac{d \text{cl}_p(\psi)}{d \psi} \bigg|_{(\psi, \psi_g)} = \frac{1}{\sqrt{n}} \frac{\partial \text{cl}(\psi, \lambda)}{\partial \psi} \bigg|_{(\psi, \lambda_g)} + \frac{1}{n} \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi, \lambda_g)} \sqrt{n}(\hat{\lambda}(\psi_g) - \lambda_g)
\]
(I) and (II) in Eq.(16) become;

\[
\frac{1}{\sqrt{n}} \frac{\partial c_l(\psi, \lambda)}{\partial \psi} \bigg|_{(\psi_g, \lambda_g)} \rightarrow N(0, J_{\psi\psi}(\psi_g, \lambda_g)) \quad \text{(by CLT)}
\]

\[
\frac{1}{n} \frac{\partial^2 c_l(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi_g, \lambda_g)} \rightarrow E_g \left( \frac{\partial^2 c_l(\psi, \lambda)}{\partial \psi \partial \lambda} \right) \bigg|_{(\psi_g, \lambda_g)} \quad \text{(by LLN)}
\]

\[
= -H_{\psi\lambda}(\psi_g, \lambda_g)
\]

What about (III) in Eq.(16)?

Note that \( \hat{\lambda}(\psi_g) \) is the solution to \( \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\hat{\lambda}(\psi_g)} = 0 \). Then a Taylor expansion of \( \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\hat{\lambda}(\psi_g)} \) about \( \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\lambda_g} \) gives,

\[
\frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\hat{\lambda}(\psi_g)} = 0 = \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\lambda_g} + \frac{d^2 c_l(\psi_g, \lambda)}{d\lambda^2} \bigg|_{\lambda_g} (\hat{\lambda}(\psi_g) - \lambda_g) + R_{n^*}^{**}.
\]

(17)

Dividing both sides by \( \sqrt{n} \), we get

\[
\frac{1}{\sqrt{n}} \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\hat{\lambda}(\psi_g)} = \frac{1}{\sqrt{n}} \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\lambda_g} + \frac{1}{n} \frac{d^2 c_l(\psi_g, \lambda)}{d\lambda^2} \bigg|_{\lambda_g} \sqrt{n}(\hat{\lambda}(\psi_g) - \lambda_g) + \frac{R_{n^*}^{**}}{\sqrt{n}}.
\]

(18)

In (18), \( \frac{R_{n^*}^{**}}{\sqrt{n}} = \frac{1}{n} \frac{d^3 c_l(\psi_g, \lambda)}{d\lambda^3} \bigg|_{t} \sqrt{n}(\hat{\lambda}(\psi_g) - \lambda_g)^2 \) where \( \lambda_g - t \leq \delta \). Then by A6 and \( (\hat{\lambda}(\psi_g) - \lambda_g) \rightarrow^p 0 \), the following argument holds (Knight, 2000, chap.5),

\[
(\hat{\lambda}(\psi_g) - \lambda_g) \frac{1}{n} \frac{d^3 c_l(\psi_g, \lambda)}{d\lambda^3} \bigg|_{t} \rightarrow^p 0.
\]

(19)

Then (III) in Eq.(16) becomes

\[
\sqrt{n}(\hat{\lambda}(\psi_g) - \lambda_g) \rightarrow^p -\frac{1}{\sqrt{n}} \frac{dc_l(\psi_g, \lambda)}{d\lambda} \bigg|_{\lambda_g} - \frac{1}{n} \frac{d^2 c_l(\psi_g, \lambda)}{d\lambda^2} \bigg|_{\lambda_g} \frac{N(0, J_{\lambda\lambda}(\psi_g, \lambda_g))}{D_{\lambda\lambda}(\psi_g, \lambda_g)}
\]

(20)
Substituting (20) in (16)

\[
A_n = \frac{1}{\sqrt{n}} \left. \frac{dcl_p(\psi)}{d\psi} \right|_{(\psi_g)} \xrightarrow{d} z_1 - H_{\psi\lambda}(\psi_g, \lambda_g) \frac{z_2}{H_{\lambda\lambda}(\psi_g, \lambda_g)}
\]

where

\[
\begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \xrightarrow{d} N\left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} J_{\psi\psi}(\psi_g, \lambda_g) & J_{\psi\lambda}(\psi_g, \lambda_g) \\ J_{\lambda\psi}(\psi_g, \lambda_g) & J_{\lambda\lambda}(\psi_g, \lambda_g) \end{bmatrix} \right)
\]

Then

\[
A_n \xrightarrow{d} N\left( 0, [J_{\psi\psi}(\psi_g, \lambda_g) + \frac{[H_{\psi\lambda}(\psi_g, \lambda_g)]^2}{H_{\lambda\lambda}(\psi_g, \lambda_g)}] J_{\lambda\lambda}(\psi_g, \lambda_g) - 2\frac{H_{\psi\lambda}(\psi_g, \lambda_g)}{H_{\lambda\lambda}(\psi_g, \lambda_g)} J_{\psi\lambda}(\psi_g, \lambda_g)] \right)
\]

(21)

What about \(B_n\) in (12)?

\[
B_n = \frac{1}{n} \left. \frac{d^2cl_p(\psi)}{d\psi^2} \right|_{(\psi_g)}
\]

(22)
where

\[
\frac{d^2 c_l^p(\psi)}{d\psi^2} \bigg|_{(\psi_g)} = \frac{d}{d\psi} \left[ \frac{d c_l^p(\psi)}{d\psi} \right] \bigg|_{(\psi_g)}
\]

\[
= \frac{\partial}{\partial \psi} \left[ \frac{\partial c_l(\psi, \lambda)}{\partial \psi} + \frac{\partial c_l(\psi, \lambda)}{\partial \lambda} \frac{d \lambda}{d\psi} \right] \bigg|_{(\psi_g, \lambda(\psi_g))}
\]

\[
= \frac{\partial^2 l c_l(\psi, \lambda)}{\partial \psi^2} \bigg|_{(\psi_g, \lambda(\psi_g))} + \frac{\partial^2 c_l(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi_g, \lambda(\psi_g))} \frac{d \lambda}{d\psi} \bigg|_{(\psi_g)}
\]

\[
+ \left\{ \frac{\partial^2 c_l(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi_g, \lambda(\psi_g))} + \frac{\partial^2 c_l(\psi, \lambda)}{\partial \lambda^2} \bigg|_{(\psi_g, \lambda(\psi_g))} \frac{d \lambda}{d\psi} \bigg|_{(\psi_g)} \right\} \frac{d \lambda}{d\psi} \bigg|_{(\psi_g)}
\]

\[
+ \frac{d^2 \lambda}{d\psi^2} \bigg|_{(\psi_g)} \frac{\partial c_l(\psi, \lambda)}{\partial \lambda} \bigg|_{(\psi_g, \lambda(\psi_g))} \left[ \frac{d \lambda}{d\psi} \bigg|_{(\psi_g)} \right]^{2}
\]

\[
\square
\]
Why is $R_n$ of $O_p(n^{-1/2})$ in Eq.(12)? $R_n = \frac{1}{\delta_n^{1/2}} \frac{d^3 cl_p(\psi)}{d\psi^3} \bigg|_t$ where $|\psi - t| \leq \delta$.

\[
\frac{d^3 cl_p(\psi)}{d\psi^3} \bigg|_t = \frac{d}{d\psi} \left[ \frac{\partial^2 l \partial\lambda}{\partial\psi^2} \bigg|_{(t,\hat{\lambda}(t))} + \frac{2 \partial^2 l \partial\lambda}{\partial\psi \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right] \\
+ \frac{\partial^2 l \partial\lambda}{\partial\psi \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} \left( \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right)^2 \\
= \frac{d}{d\psi} \left[ \frac{\partial^2 l \partial\lambda}{\partial\psi^2} \bigg|_{(t,\hat{\lambda}(t))} \right] + \frac{d}{d\psi} \left[ \frac{2 \partial^2 l \partial\lambda}{\partial\psi \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right] \\
+ \frac{d}{d\psi} \left[ \frac{\partial^2 l \partial\lambda}{\partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} \bigg( \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right)^2 \\
A_1 = \left[ \frac{\partial^3 l \partial\lambda}{\partial\psi \partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} + \frac{\partial^3 l \partial\lambda}{\partial\psi^2 \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right] \\
A_2 = 2 \left[ \left\{ \frac{\partial^3 l \partial\lambda}{\partial\psi^2 \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} + \frac{\partial^3 l \partial\lambda}{\partial\psi \partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right\} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right] \\
+ \frac{\partial^3 l \partial\lambda}{\partial\psi \partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} \frac{d^2 \hat{\lambda}(\psi)}{d\psi^2} \bigg|_t \\
A_3 = \left[ \frac{\partial^3 l \partial\lambda}{\partial\psi \partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} + \frac{\partial^3 l \partial\lambda}{\partial\psi^2 \partial\lambda} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right] \bigg( \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \right)^2 \\
+ 2 \frac{\partial^3 l \partial\lambda}{\partial\psi \partial\lambda^2} \bigg|_{(t,\hat{\lambda}(t))} \frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t \frac{d^2 \hat{\lambda}(\psi)}{d\psi^2} \bigg|_t \\
\]

From Lemma 2 below, $\frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_t = O_p(1)$. By taking the second derivative of $\frac{d\hat{\lambda}(\psi)}{d\psi}$ with respect to $\psi$, it is seen that $\frac{d^2 \hat{\lambda}(\psi)}{d^2 \psi} \bigg|_t = O_p(1)$. Also, following the arguments presented in Lemma 1, we observe that the second and
higher order derivatives of composite log-likelihood functions in $A_1$, $A_2$ and $A_3$
are of $O_p(n)$, since the mean of the log likelihood derivatives are of order $O(n)$
(they are $O(1)$ for one observation) and the log composite likelihood is a finite
sum of log likelihoods, e.g. the first term in $A_1$ is $O_p(n)$ since
\[
\frac{1}{n} \frac{\partial^3 \text{cl}(\psi, \lambda)}{\partial \psi^3} \bigg|_{(t, \hat{\lambda}(t))} \rightarrow E_g \left( \frac{\partial^3 \text{cl}(\psi, \lambda)}{\partial \psi^3} \bigg|_{(t, \lambda(t))} \right).
\]
\[\therefore R_n = O_p(n^{-1/2}).\]

Lemma 1. (Royall, 2000)
\[
\frac{1}{n} \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi^2} \bigg|_{(\psi_g, \hat{\lambda}(\psi_g))} \rightarrow -H_{\psi\psi}(\psi_g, \lambda_g)
\]
\[
\frac{1}{n} \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{(\psi_g, \hat{\lambda}(\psi_g))} \rightarrow -H_{\psi\lambda}(\psi_g, \lambda_g)
\]
This follows from the Law of Large Numbers, since $\hat{\lambda}(\psi)$ is the MLE in the one
dimensional model with a fixed $\psi$.

Lemma 2. (Royall, 2000)
\[
\frac{d\hat{\lambda}(\psi)}{d\psi} \bigg|_{(\psi_g)} \rightarrow -\frac{H_{\psi\lambda}(\psi_g, \lambda_g)}{H_{\lambda\lambda}(\psi_g, \lambda_g)} \quad (23)
\]
Proof. Let $g(\psi, \hat{\lambda}(\psi)) = \frac{\partial d(\psi, \lambda)}{\partial \lambda} \bigg|_{\hat{\lambda}(\psi)}$. Since $g(\psi, \hat{\lambda}(\psi)) = 0$ \quad \forall \psi, $g(\psi, \hat{\lambda}(\psi))$ is a constant. Thus $dg/d\psi = 0$.
\[
\frac{dg}{d\psi} = \frac{\partial g(\psi, \lambda)}{\partial \psi} \bigg|_{\hat{\lambda}(\psi)} + \frac{\partial g(\psi, \lambda)}{\partial \lambda} \bigg|_{\hat{\lambda}(\psi)} \frac{d\hat{\lambda}(\psi)}{d\psi}
\]
\[0 = \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{\hat{\lambda}(\psi)} + \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi^2} \bigg|_{\hat{\lambda}(\psi)} \frac{d\hat{\lambda}(\psi)}{d\psi}
\]
Thus $\frac{d\hat{\lambda}(\psi)}{d\psi} = \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi \partial \lambda} \bigg|_{\hat{\lambda}(\psi)} \frac{\partial^2 \text{cl}(\psi, \lambda)}{\partial \psi^2} \bigg|_{\hat{\lambda}(\psi)}$. The conclusion follows from Lemma 1. \[\square\]
Then

$$B_n \to -H_{\psi\psi} + H_{\psi\lambda} \frac{H_{\psi\lambda}}{H_{\psi\psi}}$$

Then (12) becomes;

$$cl_p(\theta_1) - cl_p(\theta_g) \xrightarrow{d} N(-\frac{c^2}{2}a, c^2b) \quad (24)$$

where

$$a = H_{\psi\psi} - H_{\psi\lambda} \frac{H_{\psi\lambda}}{H_{\psi\psi}} = H_{\psi\psi}(\psi_g, \lambda_g)^{-1}$$

$$b = [J_{\psi\psi}(\psi_g, \lambda_g) + \left(\frac{H_{\psi\lambda}(\psi_g, \lambda_g)}{H_{\lambda\lambda}(\psi_g, \lambda_g)}\right)^2 J_{\lambda\lambda}(\psi_g, \lambda_g) - 2 \frac{H_{\psi\lambda}(\psi_g, \lambda_g)}{H_{\lambda\lambda}(\psi_g, \lambda_g)} J_{\psi\lambda}(\psi_g, \lambda_g)] \quad \text{(from (21))}$$

We see that (24) does not produce a bump function (the mean is not the negative half of the variance). If we take \(\left(\frac{cl_p(\psi_1)}{cl_p(\psi_g)}\right)^{a/b}\) then

$$\left(\frac{cl_p(\psi_1)}{cl_p(\psi_g)}\right)^{a/b} \to N\left(-\frac{c^2 a^2}{2 b}, \frac{c^2 a^2}{b}\right),$$

which results in a bump function. Then the probability of misleading evidence will be

$$P_g \left\{ \left(\frac{cl_p(\psi_1)}{cl_p(\psi_g)}\right)^{a/b} \geq k \right\} \to \Phi \left\{ -\frac{(ca/b^{1/2})}{2} - \log(k) \left(\frac{ca/b^{1/2}}{ca/b^{1/2}}\right) \right\} \quad \text{(the bump function).}$$

In Theorem 2, \(c^* = ca/b^{1/2}\).

**B Generating correlated binary data**

The method in Emrich and Piedmonte (1991) for generating correlated binary data uses a discretised normal approach to generate correlated binary variates with speci-
fied marginal probabilities and pairwise correlations. Suppose we want to generate a $k$-dimensional correlated binary vector, $\mathbf{Y} = (Y_1, \ldots, Y_k)$ given $\mathbf{X} = (X_1, \ldots, X_k)$, such that $p_i = E[Y_i | x_i]$ for $i = 1, \ldots, k$ and $p_{ij} = E[Y_i Y_j | x_i, x_j] = Pr(Y_i = 1, Y_j = 1 | x_i, x_j)$ for $i = 1, \ldots, k - 1$ and $j = 2, \ldots, k$. There are different approaches to quantify the dependence between a pair of binary observations. One approach is to quantify the dependence using the correlation between $Y_i$ and $Y_j$, however, the correlation gets constrained depending on the marginal probabilities, $p_i$ and $p_j$ (Prentice, 1988). Here, we use the association via the odds ratio (Dale, 1986). It is the ratio of the odds $Y_i = 1$ given that $Y_j = 1$ and the odds of $Y_i = 1$ given that $Y_j = 0$, which is interpreted as the odds of concordant pairs to discordant pairs.

$$
\psi_{ij} = \frac{Pr(Y_i = 1 | Y_j = 1, x_i, x_j) / Pr(Y_i = 0 | Y_j = 1, x_i, x_j)}{Pr(Y_i = 1 | Y_j = 0, x_i, x_j) / Pr(Y_i = 0 | Y_j = 0, x_i, x_j)}
= \frac{Pr(Y_i = 1, Y_j = 1 | x_i, x_j) Pr(Y_i = 0, Y_j = 0 | x_i, x_j)}{Pr(Y_i = 1, Y_j = 0 | x_i, x_j) Pr(Y_i = 0, Y_j = 0 | x_i, x_j)}
= \frac{p_{ij}(1 - p_i - p_j + p_{ij})}{(p_i - p_{ij})(p_j - p_{ij})}
$$

from Table 5

| $Y_j = 1$ | $Y_j = 0$ |
|---|---|
| $Y_i = 1$ | $p_{ij}$ | $p_i - p_{ij}$ | $p_i$ |
| $Y_i = 0$ | $p_j - p_{ij}$ | $1 - p_i - p_j + p_{ij}$ | $1 - p_i$ |

Thus, the joint probability of $p_{ij}$ is written in terms of the marginal probabilities, $p_i$ and $p_j$ and the odds ratio, $\psi_{ij}$. (Plackett (1965).

$$
p_{ij} = \begin{cases} 
\frac{1 + (p_i + p_j)(\psi_{ij} - 1) - S(p_i, p_j, \psi_{ij})}{2(\psi_{ij} - 1)} & \text{if } \psi_{ij} \neq 1, \\
p_i p_j & \text{if } \psi_{ij} = 1,
\end{cases}
$$  

(25)

43
where

\[ S(p_i, p_j, \psi_{ij}) = \sqrt{\left\{1 + (p_i + p_j)(\psi_{ij} - 1)\right\}^2 + 4\psi_{ij}(1 - \psi_{ij})p_ip_j}, \]

for \( p_i, p_j \in (0, 1) \), \( \psi_{ij} \geq 0 \). If \( Y_i \) and \( Y_j \) are independent then \( \psi_{ij} = 1 \).

Also, the pairwise correlation, \( \text{corr}(Y_i, Y_j | x_i, x_j) = \delta_{ij} \) is

\[ \delta_{ij} = \frac{p_{ij} - p_ip_j}{(p_i(1 - p_i)p_j(1 - p_j))^{1/2}}, \quad (26) \]

Now, let \( Z = (Z_1, ..., Z_k) \) be a standard multivariate random variable with mean 0 and correlation matrix \( \Sigma = (\rho_{ij}) \) with \( i = 1, ..., k - 1 \) and \( j = 2, ..., k \). Then set \( Y_i = 1 \) if \( Z_i \leq z(p_i) \) and set \( Y_i = 0 \) otherwise for \( i = 1, ..., k \), where \( z(p_i) \) is the \( p_i^{th} \) quantile of the standard normal distribution. This leads to

\[ E[Y_i | x_i] = Pr(Y_i = 1 | x_i) = Pr(Z_i \leq z(p_i)) = p_i, \quad (27) \]

and

\[ E[Y_i Y_j | x_i, x_j] = Pr(Y_i = 1, Y_j = 1 | x_i, x_j) = Pr(Z_i \leq z(p_i), Z_j \leq z(p_j)) = \Phi(z(p_i), z(p_j), \rho_{ij}), \]

where

\[ \Phi(z(p_1), z(p_2), \rho_{ij}) = \int_{-\infty}^{z(p_1)} \int_{-\infty}^{z(p_2)} f(z_1, z_2, \rho) dz_1 dz_2, \]

and \( f(z_1, z_2, \rho) \) is the probability density function of a standard bivariate normal random variable with mean 0 and correlation coefficient \( \rho \).

Note from Eq.(26) that \( E[Y_i Y_j | x_i, x_j] = p_ip_j + \delta_{ij} (p_i(1 - p_i)p_j(1 - p_j))^{1/2} \). Then,

\[ \Phi(z(p_i), z(p_j), \rho_{ij}) = p_ip_j + \delta_{ij} (p_i(1 - p_i)p_j(1 - p_j))^{1/2}. \quad (28) \]

To solve Eq.(28) for \( \rho_{ij} \), Emrich and Piedmonte (1991) suggested using a bisection technique. This method does not ensure that the pairwise probabilities \( p_{ij} \), or the correlation matrix composed of binary correlations \( (\delta_{ij}) \) are valid. Below are the compatibility conditions that are needed to be checked (Leisch et al., 1998):
1. $0 \leq p_i \leq 1$ for $i = 1, ..., k$.

2. $\max(0, p_i + p_j - 1) \leq p_{ij} \leq \min(p_i, p_j)$ for $i \neq j$.

3. $p_i + p_j + p_l - p_{ij} - p_{il} - p_{jl} \leq 1$ for $i \neq j, j \neq l, l \neq i$.

These conditions are necessary in order to get a nonnegative joint mass function for $Y$ (Emrich and Piedmonte, 1991).

We define the bivariate joint probability, $p_{ij}$, in terms of the marginal probabilities $p_i$ and $p_j$, and an odds ratio $\psi_{ij}$ (Eq (25)). However, for this simulation method, we need to use pairwise correlations $\delta_{ij}$ instead of $\psi$. The relationship between $\delta_{ij}$, and $\psi_{ij}$ can be easily established when we plug Eq.(25) in Eq.(26).

Below, we provide a step-by-step summary of the simulation algorithm for generating a $k$-dimensional binary vector:

1. Set $\beta_0$, $\beta_1$ and $\psi$ values. Determine the marginal probabilities from the logistic model and second order probabilities in Eq.(25). Check the compatibility conditions. Calculate pairwise correlations $\delta_{ij}$ between each binary pair.

2. Calculate $z(p_i)$ from Eq.(27).

3. Solve Eq.(28) to obtain the elements of the correlation matrix $\Sigma = (\rho_{ij})$ for the multivariate normal distribution.

4. Generate a $k$-dimensional multivariate normal vector $Z$ with mean $z(p_i)$ and correlation matrix $\Sigma = (\rho_{ij})$.

5. Set $y_i = 1$ if $z_i \leq z(p_i)$, and $y_i = 0$ otherwise, for $i = 1, ..., k$.

We check the compatibility conditions in Step 1 using the R package bindata (Leisch et al. (2012)), and for Steps 2–5, we used the R package mvtBinaryEP (By and Qaqish (2011)) in the R Statistical Software. This procedure generates a vector of binary variables with the desired properties, namely, $E(Y_i) = p_i$ and $\text{corr}(Y_i, Y_j \mid x_i x_j) = \delta_{ij}$. Other methods for generating correlated data can be found in Jin (2010).

Another important point is that this method generates correlated binary data that satisfy the first and second order marginal distributions. There might be more than one joint distribution that generate the same lower dimensional marginal distributions, in which case the inference from a composite likelihood approach will be the
same for that family of distributions (Varin et al., 2011). This property of composite likelihood inference is viewed as being robust by many authors (Xu (2012), Varin et al. (2011), Jin (2010)).

C Finding the profile maximum likelihood estimates

We follow the steps below to find the profile maximum likelihood estimates (MCLE) of the parameter of interest, for example, when the parameter of interest is $\beta_1$ and $\theta = (\beta_0, \beta_1)$.

1. Set a grid for $\beta_1$, i.e. $\{\beta_{11}, \beta_{12}, \ldots, \beta_{1g}\}$.

2. For each $\beta_{1i}$, $i = 1, \ldots, g$, maximize the composite likelihood chosen with respect to the nuisance parameters as a function of $\beta_{1i}$. Obtain the composite likelihood value for each $(\beta_{1i}, \hat{\beta}_0(\beta_{1i}))$. Note that $(\hat{\beta}_0(\beta_{1i}))$ is the MCLE when $\beta_1$ is taken as fixed. For this, we use the Newton Raphson algorithm which we coded using the R Statistical Software (R Core Team (2015)).

3. Find the profile MCLE, $\hat{\beta}_{1\text{CL}_p}$, which maximizes the composite likelihoods calculated in Step 2.

D The composite likelihood constructed from pairwise margins

When the dependence parameter is also of interest, we need to construct the composite likelihood from pairwise (or higher order) likelihood components (Varin et al., 2011). The composite likelihood constructed from pairwise likelihood components is,

$$CL_{\text{pair}}(\beta_0, \beta_1, \psi) = \prod_{i=1}^{N} \left[ \prod_{j=1}^{n_i-1} \prod_{k=j+1}^{n_i} P(Y_{ij} = y_{ij}, Y_{ik} = y_{ik} \mid x_i) \right]^{1/(n_i - 1)},$$

where $\prod_{j=1}^{n_i-1} \prod_{k=j+1}^{n_i} P(Y_{ij} = y_{ij}, Y_{ik} = y_{ik} \mid x_i)$ denotes the pairwise likelihood for the $i^{th}$ family (Table 5 and Eq. (25)). The weight $1/(n_i - 1)$ is used to weigh the contribution of each family according to its size when the parameter of interest is the
marginal parameter, since each observation in a family of size \( k \) presents in \( k-1 \) pairs (Zhao and Joe, 2005).

When the parameter of interest is \( \beta_1 \), we can determine the profile composite likelihood \( CL_p(\beta_1) = \max_{\beta_0, \beta_1} \{CL_{pair}(\beta_0, \beta_1, \psi)\} \) and compute the profile composite likelihood estimate, \( \hat{\beta}_1CL_{pair} = \max_{\beta_1} \log CL_p(\beta_0, \beta_1, \psi) \). However, when we want to get inference about \( \psi \), we use the composite likelihood in Eq.(29) without the weights for families. We do not need to use the weights since the dependence parameter \( \psi \) appears the right amount of times in the pairwise likelihood function for a family of size \( k \), where there are \( k-1 \) pairs.

\[
CL_{pair}^\psi(\beta_0, \beta_1, \psi) = \prod_{i=1}^N \left[ \prod_{j=1}^{n_i-1} \prod_{k=j+1}^{n_i} P(Y_{ij} = y_{ij}, Y_{ik} = y_{ik} \mid x_i) \right] \tag{30}
\]

and calculate \( CL_p(\psi) = \max_{\beta_0, \beta_1} \{CL_{pair}^\psi(\beta_0, \beta_1, \psi)\} \).

### E More simulation results

In these simulations, we consider three different family structures, where \( k \) is the family size.

1. **Sibling study with \( k = 5 \):** Data consist of only siblings, where the number of siblings is 5 in each family.

2. **Sibling study with \( k \in \{2, 3, 4, 5\} \):** Data consist of only siblings, where the number of siblings is 2, 3, 4 or 5 in each family.

3. **Family study with \( k = 5 \):** Data consist of nuclear families with 3 siblings, i.e., 2 parents and 3 offspring.

In the Sibling study with \( k = 5 \), we choose three different values for the dependence parameter \( \psi \) to indicate weak dependence \((\psi = 1.2)\), moderate dependence \((\psi = 3)\) and strong dependence \((\psi = 6)\) within family members. Here we are interested in whether the inference about \( \beta_1 \) is affected by different strengths of dependence. For the other family structures, we only take into account \( \psi = 3 \). In Table 6, for the Sibling study with \( k = 5 \) siblings, we see that as sample size increases, both composite likelihood approaches provide consistent estimates for the true parameter value \( \beta_1 \).
The results do not change whether the dependence between sibling pairs are weak or strong.

**Table 6.** Sibling study with $k = 5$. The maximum profile composite likelihood estimates of $\beta_1$, using independent and pairwise likelihood methods, under a weak, moderate and strong dependence parameter ($\psi = 1.2, 3$ and $6$) and with different numbers of families ($n$) and $\beta_0 = -1, \beta_1 = 2$.

| $\psi$ | independent | pairwise | independent | pairwise | independent | pairwise |
|-------|-------------|----------|-------------|----------|-------------|----------|
| $\psi = 1.2$ | 2.048 | 2.048 | 2.064 | 2.062 | 2.096 | 2.090 |
| $\psi = 3$ | 2.016 | 2.016 | 2.023 | 2.023 | 2.024 | 2.024 |
| $\psi = 6$ | 2.002 | 2.002 | 2.006 | 2.006 | 2.006 | 2.006 |

In Table 7, for the Sibling study with $k \in \{2, 3, 4, 5\}$, we also see that as sample size increases, both composite likelihood approaches provide consistent estimates for the true parameter value $\beta_1$.

**Table 7.** Sibling study with $k \in \{2, 3, 4, 5\}$. The maximum profile composite likelihood estimates of $\beta_1$, using independent and pairwise likelihood methods, under the moderate dependence parameter $\psi = 3$ and with different number of families $n$ and $\beta_0 = -1, \beta_1 = 2$.

| $\hat{\beta}_{1CL_p}$ | $\psi = 3$ | $\psi = 6$ |
|------------------------|-------------|-------------|
| $n$ | independent | pairwise | independent | pairwise | independent | pairwise |
| 30 | 2.106 | 2.102 | 2.106 | 2.102 |
| 100 | 2.029 | 2.029 |
| 300 | 2.008 | 2.008 |
| 500 | 2.006 | 2.006 |
| 1000 | 2.002 | 2.002 |

In Table 8, for the Family study with $k = 5$, we see that as sample size increases, the independent likelihood provides consistent estimates for the true parameter value $\beta_1$. However, the pairwise likelihood does not. This is due to that fact that the two different parameter for dependence, $\psi_1$ and $\psi_2$, induce some constraints on the true mean parameters ($\beta_0, \beta_1$). This changes the meaning of the mean parameters that are represented by the pairwise likelihood.
Table 8. Family study with $k = 5$. The maximum profile composite likelihood estimates of $\beta_1$, using independent and pairwise likelihood methods, under a moderate dependence parameter $\psi = 3$ and with different number of families ($n$) and $\beta_0 = -1$, $\beta_1 = 2$.

| $n$   | independent | pairwise |
|-------|-------------|----------|
| 30    | 2.062       | 1.938    |
| 100   | 2.022       | 1.915    |
| 300   | 2.003       | 1.898    |
| 500   | 2.003       | 1.899    |
| 1000  | 2.002       | 1.899    |

In Table 9, we see that as sample size increases, the pairwise likelihood provides consistent estimates for the true parameter value $\psi$.

Table 9. Sibling study with $k = 5$. The maximum profile composite likelihood estimates of $\delta = \log(\psi)$, using the pairwise likelihood method and with different number of families ($n$) and $\beta_0 = -1$, $\beta_1 = 2$, $\delta = \log(3) = 1.099$.

| $n$   | 30 | 100 | 300 | 500 | 1000 |
|-------|----|-----|-----|-----|------|
| $\delta_{CL_p}$ | 1.031 | 1.079 | 1.092 | 1.094 | 1.096 |
