Environmental effects on mode II fracture toughness of unidirectional E-glass/vinyl ester laminated composites

https://doi.org/10.1515/secm-2021-0028
received November 19, 2020; accepted February 26, 2021

Abstract: In this article, mode II fracture toughness \(G_{\text{IIc}}\) of unidirectional E-glass/vinyl ester composites subjected to sulfuric acid aging is studied at two different temperatures (25 and 90°C). Specimens were manufactured using the hand lay-up method with the [0]_{20} stacking sequence. To study the effects of environmental conditions, samples were exposed to 30 wt% sulfuric acid at room temperature (25°C) for 0, 1, 2, 4, and 8 weeks. Some samples were also placed in the same solution but at 90°C and for 3, 6, 9, and 12 days to determine the interlaminar fracture toughness at different aging conditions. Fracture tests were conducted using end notched flexure (ENF) specimens according to ASTM D7905. The results obtained at 25°C showed that mode II fracture toughness increases for the first 2 weeks of aging and then it decreases for the last 8 weeks. It was also found that the flexural modulus changes with the same trend. Based on the results of the specimens aged at 90°C, a sharp drop in fracture toughness and flexural modulus with a significant decrease in maximum load have been observed due to the aging. Finite element simulations were performed using the cohesive zone model (CZM) to predict the global response of the tested beams.

Keywords: acid aging, mode II fracture toughness, unidirectional composites, degradation

Nomenclature

- \(a\): crack length
- \(a_0\): initial crack length
- \(b\): width of the ENF specimen
- \(C\): compliance
- \(E_1\): longitudinal modulus
- \(E_2\): transvers modulus
- \(E_{\text{fx}}\): flexural modulus
- \(G\): mode I strain energy release rate
- \(G_{\text{II}}\): mode II strain energy release rate
- \(G_{\text{IC}}\): mode I critical strain energy release rate
- \(G_{\text{IIC}}\): mode II critical strain energy release rate
- \(k_p\): initial stiffness of cohesive zone model
- \(G_{\text{12}}\): in-plane shear modulus
- \(\tau_{\text{max}}\): maximum cohesive shear traction
- \(P\): applied load
- \(\delta^*\): separation
- \(\delta_i^*\): separation at initiation of damage
- \(\delta_f^*\): separation at final point of damage
- \(m\): slope of the regression line
- \(l_s\): span length
- \(l_p\): half of the total length of the specimen
- \(\delta\): load line displacement
- \(v_{12}\): in-plane Poisson’s ratio

1 Introduction

Nowadays, polymeric matrix composites are widely used in a variety of industrial sectors especially in aerospace
and automotive industries due to their advantages such as corrosion reduction. Hence, it is vital to characterize the properties and determine the damage mechanisms of these materials. Delamination is one of the important destructive phenomena and a critical failure mode, which occurred in composite structures as a result of high peel loads and the low transverse strength of the composites [1–6]. The presence of delamination will lead to the premature buckling of the laminate, intrusion of moisture, stiffness degradation, loss of fatigue life, and even the collapse of the structure [6–9]. Therefore, the study of delamination phenomena in laminated composites and their fracture toughness to predict the failure has significant importance [10]. Temperature variation, humidity, and impact are important factors involved in the occurrence of delamination [11]. In the selection of fiber and resin, the application of the composite and also environmental factors facing them have a significant role. The resistance of composite materials against delamination is significantly affected by environmental conditions such as temperature and humidity, which may occur during service or maintenance programs [12]. Mechanical aging level in composite materials is a function of aging time, and its rate depends on the environmental condition and the applied load. The variety of influencing parameters makes accurate prediction of the aging process of composites difficult [13]. Therefore, most studies analyze the effects of environmental conditions on the mechanical properties of composite laminates, experimentally. Zenasni et al. [14,15] investigated experimental characterization of the mechanical properties of three types of woven fabric composites taking into account the effects of hygrothermal and hygro–thermo–mechanical aging. The specimens were exposed to moisture–thermal and moisture–thermal–mechanical aging conditions at 70°C for 0, 30, 60, 120, and 180 days. The mechanical characterization was carried out using mode I, double cantilever beam (DCB), and mode II, ENF interlaminar fracture tests. Woven (2/2 Twill, 8-Harness Satin) glass fiber and 8-Harness Satin carbon fiber were used. The matrix was polyetherimide (PEI). The results of mode I for the hygrothermal condition showed that delamination energy experiences a lower loss over the aging time for the 8-Harness Satin fabric instead of the 2/2 Twill fabric. Moreover, it was found that the delamination energy decreases with exposure time for specimens reinforced with glass fibers rather than specimens reinforced with carbon fibers. Similar to mode I, the result of mode II showed that 2/2 Twill specimens were less resistant to fracture than the 8-Harness Satin. Also, the samples reinforced by carbon fiber were found to be more brittle than samples reinforced by glass fiber. Experimental mode I fracture characterization of samples that were exposed to hygro–thermo–mechanical aging conditions showed that the samples reinforced by carbon fiber and glass fiber have a slight decrease in resistance. Conversely, the glass fiber-reinforced 8-Harness Satin material continued to behave strangely as in hygrothermal aging. Its strength was improved in the first 30 days, and this property was subsequently maintained until 180 days. In mode II fracture, the behavior of three materials was very similar to that of mode I, although the behavior of the glass fiber reinforced 8-Harness Satin material is even more anomalous. Zhao et al. [16] investigated the effects of seawater immersion on the delamination behavior of a woven E-glass/bismaleimide (BMI) composite at different temperatures (25, 50, and 80°C) for 6,000 h under mode I, mode II, and mixed-mode I/II loadings. The results showed that for mode I DCB tests, long-term seawater exposure caused a significant decrease (25%) in fracture toughness for the samples immersed at 80°C. However, for the specimens immersed at 50°C, the initiation of the delamination was unaffected, while the propagation resistance increased with the delamination growth. In the case of the mode II ENF tests, the results showed an unstable delamination growth. Although the fracture toughness decreased for samples immersed at 50°C, this parameter increased significantly for specimens immersed at 80°C. In the case of mixed-mode tests, the seawater exposure and increase in the immersion temperature would generally decrease the mixed-mode fracture toughness. It is worth noting that due to the plasticization of the matrix and higher ductility of the specimen after immersion, most of the wet specimens generally showed increased resistance against delamination. Scida et al. [17] studied the effects of accelerated aging conditions on specimens manufactured by woven fabrics kept for 1,300 h at 70°C with 95% relative humidity. The materials studied in their research were two composites composed of glass fiber reinforcement (twill and satin weave) with two types of epoxy resin matrixes (120°C class called R1 and a 180°C class called R2). Interlaminar delamination tests were carried out on the DCB specimens for mode I, ENF specimens for mode II, and mixed-mode bending (MMB) specimens for the mixed-mode loading condition. Also, to investigate the parameters of composite degradation under loading and aging conditions and understand damage mechanisms, techniques such as acoustic emissions and microscopic observations were conducted. The results showed that the R1 epoxy matrix was very absorbent, and the fibers did not protect the laminated composites, which affects the final mechanical properties of
laminates. However, the R2 matrix offers efficient fibers protection against aging, and consequently, the mechanical properties remain almost unchanged.

Srivastava and Hogg [18] investigated the effect of moisture on the fracture toughness of mode I and mode II of aluminum tri-hydrate and polyethylene filled and unfilled quasi-isotropic glass fiber–reinforced epoxy-vinyl ester resin (GFRP) composites. Specimens were immersed in water at room temperature (20°C) for 8 months and at an interval of every 2 months, and the fracture energy in mode I ($G_{lc}$) and the mode II fracture energy ($G_{IIC}$) values were obtained. Also, some samples were exposed to hot water at 40°C. The results indicated that the moisture content and diffusion coefficients increase with the increase of the weight of the filler content. Also in the case of mode I, the toughness of all composites increased with an increase in moisture uptake. However, the mode II toughness was relatively unaffected. Selzer and Friedrich [19] investigated the effect of moisture absorption on the mode II fracture toughness of unidirectional carbon fiber composites. In their study, three different matrices including two thermosetting matrices (unmodified and toughness-modified epoxy [EP and EPmoa]) and one thermoplastic matrix (semicrystalline polyetheretherketone [PEEK]) were used. The manufactured samples were exposed to water at different temperatures (23, 70, and 100°C) for various time periods. The results showed that although $G_{lc}$ increases with the moisture content of the samples, $G_{IIC}$ decreases with aging time.

All previous studies were limited to the experimental investigation of the effect of environmental conditions such as moisture and temperature on fracture toughness. In the current study, the effect of sulfuric acid aging at two different temperatures (25 and 90°C) on mode II fracture toughness of unidirectional E-glass/vinyl ester composites was investigated. Finite element simulation using the CZM was also performed to predict the global response of the delaminated specimens.

## 2 Experimental procedure

### 2.1 Materials and properties

In the present study, the unidirectional E-glass fibers with 200 g/m² aerial density and Hetron 922 epoxy vinyl ester resin was used as the fibers and matrix of the composite, respectively. The mechanical properties of Hetron 922 resin are presented in Table 1.

### 2.2 Specimens manufacturing

E-glass fibers with a width 170 mm and a total length of 200 mm were used. The samples were manufactured using the hand lay-up method with the [0]₂₀ stacking sequence. Teflon adhesive tape with a thickness of 13 μm was used to create the pre-crack. The number of layers in the laminated composites was considered to be 20, and cracks were created between 10th and 11th layers. The weight of the resin was approximately equal to the weight of the fibers. To improve the mechanical properties of the samples, they were exposed to ambient temperature for 24 h as initial curing and then subjected to 80°C for 4 h as the postcuring process. Figure 1 shows the schematic geometry of an ENF sample. After applying environmental conditions, they were removed from the container and washed with distilled water and then given time to lose their moisture. The geometrical properties of the delaminated beams are presented in Table 2.

### 2.3 Testing procedures

#### 2.3.1 Environmental condition

To apply the environmental conditions, two glass containers were prepared, and the samples were divided into two groups; the first group was placed in a container at 25°C and the second group was placed in another container at 90°C. Then, a two-component solution of distilled water and sulfuric acid with a concentration of 30 wt% and purity of 98 wt% were prepared and poured into the containers. To expose all the samples to the solution, a glass-shaped separator was placed between them as shown in Figure 2. According to ASTM D543 [21], the solution was stirred regularly during exposure time. Then, one of the containers was placed at 25°C for different periods (0, 1, 2, 4, and 8 weeks), and the other was heated in an electric oven at 90°C for 0, 3, 6, 9, and 12 days.

#### Table 1: Mechanical properties of Hetron 922 vinyl ester resin [20]

| Properties          | Value  |
|---------------------|--------|
| Tensile modulus ($E$) | 3.17 (GPa) |
| Tensile strength    | 86 (MPa) |
| Flexural strength   | 141 (MPa) |
| Density of liquid ($\rho$) | 1.04 (g/cm$^3$) |
| Density of solid ($\rho$) | 1.14 (g/cm$^3$) |
2.3.2 Test method

In this study, the flexure test according to ASTM D7905 [22] was carried out on ENF specimens to measure the fracture toughness of mode II and the flexural modulus of E/vinyl ester composites. In the current study, at least four specimens are tested for each condition. Specimens were tested utilizing a universal testing machine (STM-250) with a high precision load cell with the capacity of 2,000 kgf. The tests were carried out under displacement control conditions with a crosshead rate of 0.5 mm/min. According to ASTM D7905, compliance tests were conducted on the specimens with different pre-crack sizes. For this goal, the initial crack lengths were determined as 20, 25, 35, and 40 mm, while the load corresponding to each crack length was limited only to half of the maximum bearable load corresponding to crack initiation. Following each loading step, the specimens should be unloaded under displacement control conditions. It should be noted that both the loading and unloading in the compliance tests were performed at 0.5 mm/min crosshead speed. Afterward, the fracture tests were carried out on the ENF samples where the pre-crack size was set to 30 mm. By using the compliance data, the fracture energy was obtained using the following equation:

$$G_{II} = \frac{3P^2a^2}{2b},$$

where $P$ is the applied load, $a$ is the corresponding crack length, and $b$ is the width of the samples. Based on ASTM D7905, the coefficient $m$ is determined by the least square

---

Table 2: Geometrical parameters of ENF specimens

| $l_1$ (mm) | $a_0$ (mm) | $l_s$ (mm) | $b$ (mm) |

analysis on the experimental compliance \( C = \frac{\delta}{P} \) versus the crack length cubed as follows:

\[
C = A + ma^3
\]

where the coefficient \( m \) is the slope of the regression line and \( A \) is the intercept [23].

### 3 Numerical procedure

Among the common numerical methods, many researchers used the cohesive zone models as an efficient and fast convergence method to simulate the delamination initiation and propagation of composite laminates. The reported numerical results show that the cohesive zone model can be used to simulate crack initiation and propagation in different fracture modes, e.g., mode I and II and mixed mode I/II, accurately [24–27]. The constitutive equation of interface elements is based on the traction-separation law. This law has different shapes such as bilinear, trilinear, trapezoidal, and exponential forms [28]. In finite element modeling, one layer of the element with small or zero thickness is considered in the probable path of the delamination propagation. In the current study, the delamination propagation was simulated using the bilinear cohesive zone model, as illustrated in Figure 4. In this model, through the sliding between the surfaces of the delamination propagation, the shear traction in the cohesive elements increases linearly until reaching a maximum level and then, the amount of shear traction reduces in these elements until reaching zero, where a crack forms. The initiation point of damage depends on the value of maximum cohesive zone stress and the area below the bilinear law that equals the critical strain energy release rate.

In this study, the ENF sample was modeled in the two-dimensional form using ABAQUS software. To mesh the model, four-node 2D plan strain elements (CPE4) were used. Also, the cohesive layer using 2D cohesive elements (COH2D4) with 0.01 mm thickness was placed between the two arms of the ENF sample along the crack growth path. In addition, four elements were used through the thickness of each arm. In the simulation of the ENF sample, CPE4 elements with 0.25 mm length were used through the length. In this model, all three rollers were considered as the rigid type, and the surface-to-surface contact was used with the frictionless condition between the roller and the beam.

The mechanical properties of the simulated beam, which were obtained by the experimental tests according to the ASTM standard (Table 3). The 2D simulated ENF sample is shown in Figure 5.

### 4 Result and discussion

#### 4.1 Load–displacement diagram

Typical load–displacement diagrams of delaminated beams are shown in Figures 6 and 7 for the specimens aged at

![Figure 4: Bilinear cohesive zone model.](image)

![Figure 5: Two-dimensional simulated ENF specimen in ABAQUS software.](image)

| Table 3: Mechanical properties of E-glass/vinyl ester laminate |
|------------------|-----------------|-----------------|-----------------|-----------------|
| \( E_1 \) (GPa) | \( E_2 \) (GPa) | \( E_{12} \) (GPa) | \( \nu_{12} \) | \( G_{12} \) (GPa) |
| 18 | 8.1 | 17 | 0.23 | 4.2 |
25 and 90°C, respectively. The trend of the load–displacement diagram is the same for both temperatures. The beginning of the curve, which is linear, indicates that the crack has not yet started to grow in this section. After the first section, the delamination propagates, and therefore, a nonlinear behavior is observed in the load–displacement curves. It was experimentally observed that the crack initiation approximately starts near the maximum load. Therefore, this load was used to obtain the delamination toughness. Following the unstable crack growth, the stiffness decreases, corresponding to a sudden load drop in the curves. According to Figure 6, the flexural stiffness increases after the first and the second week of aging for specimens aged at 25°C. This trend declines after the 4th week and continues decreasing until the end of the 8th week. According to Figure 7, for samples aged at 90°C, a sharp drop in flexural stiffness in the samples occurs with aging time and the flexural modulus also declines. The
**Figure 10:** Numerical and experimental load–displacement curves of specimens exposed to the acidic solution at 25°C.
A decrease in this parameter is more intense compared to the trend observed for samples exposed at 25°C, which indicates the importance of temperature of the environmental conditions in this test that accelerate the aging process. Samples that were exposed to acid aging at 90°C had a sharp drop in flexural stiffness compared to that of 25°C.

### 4.2 Fracture toughness

Figure 8 provides information about the mode II fracture toughness of the specimens aged at 25°C. According to the results, the fracture toughness increases after 1 week (from 2,200 to 2,447 J/m²) and increases to a peak of 3,187 J/m² at the end of the second week. Nevertheless, the $G_{IIc}$ value declined remarkably to 2,180 J/m² by the end of the 4th week. After 8 weeks, the fracture toughness drops to 1,820 J/m². The improvement in fracture toughness at the beginning of the environmental conditions can be due to the filling of the cavities by molecules of the acidic solution, which leads to better integrity of the specimens [29]. Conversely, these changes can be due to the absorption of water in the cavities, which can continue to act as a plasticizer. Also, as the hydroxyl group in the water molecules can bond with fiber and resin and resist against delamination of the layers, the fracture toughness increases.

According to Figure 9, the fracture toughness decreases considerably from 2,200 to 1,680 J/m² at the end of the 6th day. By the end of the 9th day, the fracture toughness experiences a sharp drop before it reaches 456 J/m² at the end of the 12th day.

As mentioned earlier, by comparing the results of samples exposed to the acidic environment at 25 and 90°C, it can be concluded that the temperature accelerates the acid aging process in the acidic environmental conditions and cause a reduction in the mode II fracture toughness severely.
4.3 Numerical and experimental data comparison

By considering the flexural modulus \(E_f\) as 17 GPa, obtained experimentally, in the numerical analysis, the load–displacement curves were obtained as shown in Figure 10. For the samples exposed to the acidic solution at 25°C during different weeks, the comparison of the numerical prediction of load–displacement curves with experimental diagram indicates the accuracy of the numerical analysis. According to the following diagram, the slope of the load–displacement curves changes by aging time. As mentioned earlier, the change in the slope of the load–displacement diagram is due to the change in the flexural modulus of the samples due to aging.

To obtain the flexural modulus, three-point bending tests were conducted on the samples after they were taken out of the acidic solution. This value was used as an input in the numerical analysis. According to Figure 11, the flexural modulus remained steady by the end of the first week and experienced a significant drop at the end of the second week. This value declined gradually until 8 weeks.

According to Figure 12, which represents the maximum load of specimens exposed to the acidic solution at 25°C, the maximum load increased considerably from 857.39 to 1028.95 N at the end of the second week and then declined substantially to the minimum amount of 803.40 at the end of the 8th week.

Figure 13 compares the experimental maximum load with the numerical results. Based on the results, at the end of the second week, the experimental maximum load was higher than the numerical one; nevertheless, at other conditions, it was lower.

![Figure 1A](image1.png)  
**Figure 1A**: Numerical and experimental load–displacement curves of specimens exposed to an acidic solution at 90°C.

![Figure 1B](image2.png)
Figure 14 presents the numerical load–displacement based on the flexural modulus obtained from the experimental results for samples exposed to the acidic solution at 90°C for 3, 6, 9, and 12 days. The slope of the load–displacement curves changes more sharply, and a considerable decline is seen in the maximum load, which is more noticeable after 6 days due to changes in the flexural modulus of the tested samples.

According to Figure 15, which shows the flexural modulus for different aging times, after 3 days of aging, a sharp drop in the flexural modulus occurs, and then, there is no significant change until the 6th day. After 9 days of the application of environmental conditions, the reduction in the flexural modulus is more noticeable.

According to Figure 16, the maximum load obtained from the numerical analysis correspond to the experimental results for samples subjected to the acidic solution at 90°C decreases by aging time. Based on the experimental and numerical results from Figure 17, the maximum load of the samples exposed to the acidic environment at 90°C declines in both approaches. The maximum load obtained by the experimental approach was higher in comparison with the numerical results; nevertheless, it was lower at the end of the 12th day.

5 Conclusion

In this article, the effect of environmental conditions on mode II fracture toughness of E-glass/vinyl ester composites with the [0]_20 stacking sequence was investigated. To achieve this, ENF samples were exposed to an acidic solution at two different temperatures (25 and 90°C) for different time periods. The fracture tests were conducted...
on the specimens according to ASTM-7905 to obtain the mode II interlaminar fracture toughness. The experimental results show that the maximum load and mode II fracture toughness for samples exposed to the acidic environment at 25°C increased by the end of the second week and then decreased. In addition, the flexural modulus obtained from the three-point bending test shows that the mentioned parameter has a descending trend with respect to the aging time. It can be concluded from experimental results that for samples subjected to the acidic solution at 90°C, the flexural modulus, the maximum load, and the mode II interlaminar fracture toughness have a descending trend versus the aging time. It was found that the maximum load, flexural modulus, and interlaminar fracture toughness reduced by 68.5, 67.6, and 79.3%, respectively after 12 days. Finally, the finite element analysis was conducted by ABAQUS software using cohesive elements to simulate delaminated beam behavior. The comparison of experimental and numerical results show that the cohesive zone model is able to predict the load–displacement curves accurately.
