A Multilingual View of Unsupervised Machine Translation

Xavier Garcia *1 Pierre Foret *1 Thibault Sellam 1 Ankur P. Parikh 1

Abstract
We present a probabilistic framework for multilingual neural machine translation that encompasses supervised and unsupervised setups, focusing on unsupervised translation. In addition to studying the vanilla case where there is only monolingual data available, we propose a novel setup where one language in the (source, target) pair is not associated with any parallel data, but there may exist auxiliary parallel data that contains the other. This auxiliary data can naturally be utilized in our probabilistic framework via a novel cross-translation loss term. Empirically, we show that our approach results in higher BLEU scores over state-of-the-art unsupervised models on the WMT'14 English-French, WMT'16 English-German, and WMT'16 English-Romanian datasets in most directions. In particular, we obtain a +1.65 BLEU advantage over the best-performing unsupervised model in the Romanian-English direction.

1. Introduction
The popularity of neural machine translation systems (Kalchbrenner & Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015; Wu et al., 2016) has exploded in recent years. Those systems have obtained state-of-the-art results for a wide collection of language pairs, but they often require large amounts of parallel (source, target) sentence pairs to train (Koehn & Knowles, 2017), making them impractical for scenarios with resource-poor languages. As a result, there has been interest in unsupervised machine translation (Ravi & Knight, 2011), and more recently unsupervised neural machine translation (UNMT) (Lample et al., 2018; Artetxe et al., 2018), which uses only monolingual source and target corpora for learning. Unsupervised NMT systems have achieved rapid progress recently (Lample & Conneau, 2019; Artetxe et al., 2019; Ren et al., 2019; Li et al., 2020), largely thanks to two key ideas: one-the-fly back-translation (i.e., minimizing round-trip translation inconsistency) (Bannard & Callison-Burch, 2005; Sennrich et al., 2015; He et al., 2016; Artetxe et al., 2018) and pre-trained language models (Lample & Conneau, 2019; Song et al., 2019). Despite the difficulty of the problem, those systems have achieved surprisingly strong results.

In this work, we investigate Multilingual UNMT (M-UNMT), a generalization of the UNMT setup that involves more than two languages. Multilinguality has been explored in the supervised NMT literature, where it has been shown to enable information sharing among related languages. This allows higher resource language pairs (e.g. English–French) to improve performance among lower resource pairs (e.g., English–Romanian) (Johnson et al., 2017; Firat et al., 2016). Yet multilingual translation has only received little attention in the unsupervised literature, and the performance of preliminary works (Sen et al., 2019; Xu et al., 2019) is considerably below that of state-of-the-art bilingual unsupervised systems (Lample & Conneau, 2019; Song et al., 2019). Another line of work has studied zero-shot translation in the presence of a “pivot” language, e.g., using French-English and English-Romanian corpora to model French-Romanian (Johnson et al., 2017; Arivazhagan et al.,

2. Background and Overview

Notation: Before discussing our approach, we introduce some notation. We denote random variables by capital letters $X$, $Y$, $Z$, and their realizations by their corresponding lowercase version $x$, $y$, $z$. We abuse this convention to compactly write objects like the conditional density $p(Y = y|X = x)$ as $p(y|x)$ or the marginalized distributions $p(X = x)$ as $p(x)$, with the understanding that the lowercase variables are connected to their corresponding uppercase random variables. Given a random variable $X$, we write $\mathbb{E}_{x \sim X}$ to mean the expectation with respect to $x$, where $x$ follows the distribution of $X$. We use a similar convention for conditional distributions e.g. we write $\mathbb{E}_{y \sim p(|x)}$ to denote the expectation of $Y$ conditioned on $X = x$. Similarly, we write $H(X)$ or $H(p(x))$ to denote the entropy of the random variable $X$ i.e. $H(X) = \mathbb{E}_{x \sim X}[-\log p(x)]$. We reserve the use of typewriter font for languages e.g. $\text{En}$.

Neural Machine Translation: In bilingual supervised machine translation we are given a training dataset $\mathcal{D}_{xy}$. Each $(x, y) \in \mathcal{D}_{xy}$ is a (source, target) pair consisting of a sentence $x$ in language $X$ and a semantically equivalent sentence $y$ in language $Y$. We train a translation model using maximum likelihood:

$$L_{\text{sup}}(\theta) = \sum_{(x,y) \in \mathcal{D}_{xy}} \log p_{\theta}(y|x)$$

In neural machine translation, $p_{\theta}(y|x)$ is modelled with the encoder-decoder paradigm where $x$ is encoded into a set of vectors via a neural network $\text{enc}_{\theta}$ and a decoder neural network defines $p_{\theta}(y|\text{enc}_{\theta}(x))$. In this work, we use a transformer (Vaswani et al., 2017) as the encoder and decoder network. At inference time, computing the most likely target sentence $y$ is intractable since it requires enumerating over all possible sequences, and is thus approximated via beam search.

Unsupervised Machine Translation: The requirement of a training dataset $\mathcal{D}_{xy}$ with source-target pairs can often be prohibitive for rare or low resource languages. Bilingual unsupervised translation attempts to learn $p_{\theta}(y|x)$ using monolingual corpora $\mathcal{D}_x$ and $\mathcal{D}_y$. For each sentence $x \in \mathcal{D}_x$, $\mathcal{D}_y$ may not contain an equivalent sentence in $Y$, and vice versa.

State of the art unsupervised methods typically work as follows. They first perform pre-training and learn an initial set of parameters $\theta$ based on a variety of language modeling or noisy reconstruction objectives (Lample & Conneau, 2019; Lewis et al., 2019; Song et al., 2019) over $\mathcal{D}_x$ and $\mathcal{D}_y$. A fine-tuning stage then follows which typically uses back-translation (Sennrich et al., 2016; Lample & Conneau, 2019; He et al., 2016) that involves translating $x$ to the target...
language $Y$, translating it back to a sentence $x'$ in $X$, and penalizing the reconstruction error between $x$ and $x'$.

**Overview of our Approach:** The following sections describe a probabilistic MT framework that justifies and generalizes the aforementioned approaches. We first model the case where we have access to several monolingual corpora, pictured in Figure 1(c). We introduce light independence assumptions to make the joint likelihood tractable and derive a lower bound, obtaining a generalization of the back-translation loss. We then extend our model to include the auxiliary corpus, introducing a novel cross-translation term. To optimize our loss, we leverage the EM algorithm, giving a rigorous justification for the stop-gradient operation that is usually applied in the back-translation loss. We then extend our model to incorporate the auxiliary parallel data pictured in Figure 1(d). We demonstrate the emergence of a cross-translation loss term, which binds distinct pairs of languages together. Finally, we present our complete training procedure, based on the EM algorithm. Building upon existing work (Song et al., 2019), we introduce a pre-training step that we run before maximizing the likelihood to obtain good representations.

### 3. Multilingual Unsupervised Machine Translation

In this section, we formulate our approach for M-UNMT. We restrict ourselves to three languages, but the arguments naturally extend to an arbitrary number of languages. Inspired by the recent style transfer literature (He et al., 2020), we introduce a generative model of which the available data can be seen as partially-observed samples. We first investigate the strict unsupervised case, where only monolingual data is available. Our framework naturally leads to an aggregate back-translation loss that generalizes previous work. We then incorporate the auxiliary corpus, introducing a novel cross-translation term. To optimize our loss, we leverage the EM algorithm, giving a rigorous justification for the stop-gradient operation that is usually applied in the UNMT and style transfer literature (Lample & Conneau, 2019; Artetxe et al., 2019; He et al., 2020).

#### 3.1. M-UNMT - Monolingual Data Only

We begin with the assumption that we have three sets of monolingual data, $D_X$, $D_Y$, $D_Z$ for languages $X$, $Y$ and $Z$ respectively. We take the viewpoint that these datasets form the visible parts of a larger dataset $D_{X,Y,Z}$ of triplets $(x, y, z)$ which are translations of each other. We think of these translations as samples of a triplet $(X, Y, Z)$ of random variables and write the observed data log-likelihood as:

$$\mathcal{L}(\theta) = \mathcal{L}_{D_X} + \mathcal{L}_{D_Y} + \mathcal{L}_{D_Z}$$

Our goal however is to learn a conditional translation model $p_\theta$. We thus rewrite the log likelihood as a marginalization over the unobserved variables for each dataset as shown below:

$$\mathcal{L}(\theta) = \sum_{x \in D_X} \log \mathbb{E}_{(y, z) \sim (x, y)} p_\theta(x | y, z)$$

$$+ \sum_{y \in D_Y} \log \mathbb{E}_{(x, z) \sim (x, y)} p_\theta(y | x, z)$$

$$+ \sum_{z \in D_Z} \log \mathbb{E}_{(x, y) \sim (x, y)} p_\theta(z | x, y)$$

Learning a model for $p_\theta(x | y, z)$ is not practical since the translation task is to translate $z \rightarrow x$ without access to $y$, or $y \rightarrow x$ without access to $z$. Thus, we make the following structural assumption: given any variable in the triplet $(X, Y, Z)$, the remaining two are independent. We implicitly think of the conditioned variable as detailing the content and the two remaining variables as independent manifestations of this content in the respective languages. Using the fact that $p_\theta(x | y, z) = p_\theta(x | y) = p_\theta(x | z)$ under this assumption, we rewrite the summand in (1) as follows:

$$\log \mathbb{E}_{(y, z) \sim (x, y)} p_\theta(x | y, z) = \log \mathbb{E}_{(y, z) \sim (x, y)} \sqrt{p_\theta(x | y)p_\theta(x | z)}.$$

Next, note that all these expectations in Eq. 1, 2, and 3 are intractable to compute due to the number of possible sequences in each language. We address this problem through the Expectation Maximization (EM) algorithm (Dempster et al., 1977). We first use Jensen’s inequality:

$$\log \mathbb{E}_{(y, z) \sim (y, z)} p_\theta(x | y, z) = \log \mathbb{E}_{(y, z) \sim (y, z)} p_\theta(x | y, z) p(y, z)$$

$$= \log \mathbb{E}_{(y, z) \sim (y, z)} p_\theta(x | y, z) p(y, z)$$

$$= \mathbb{E}_{(y, z) \sim (y, z)} [\log p_\theta(x | y, z) + \log p(y, z)]$$

$$+ H(p_\theta(y, z | x))$$

Since the entropy of a random variable is always non-negative, we can bound the quantity on the right from below as follows:

$$\log \mathbb{E}_{(y, z) \sim (y, z)} p_\theta(x | y, z) \leq \mathbb{E}_{(y, z) \sim (y, z)} [\log p_\theta(x | y, z) + \log p_\theta(y, z)]$$

$$\leq \frac{1}{2} \mathbb{E}_{y \sim p_\theta(y | x)} \log p_\theta(x | y)$$

$$+ \frac{1}{2} \mathbb{E}_{z \sim p_\theta(z | x)} \log p_\theta(x | z)$$

$$+ \mathbb{E}_{(y, z) \sim (y, z)} \log p(y, z)$$

This is actually an equality in this case since $p_\theta(x | y, z) p(y, z) = p(x)$ and hence the expectant does not actually depend on $y$ or $z$. 

---

1This is actually an equality in this case since $p_\theta(x | y, z) p(y, z) = p(x)$ and hence the expectant does not actually depend on $y$ or $z$. 

---
Applying the above strategy to (2) and (3) and rearranging terms gives us:

\[
\mathcal{L}(\theta) \geq \frac{1}{2} \sum_{y \sim p_{\theta}(|x|)} \log p_\theta(x|y) + \frac{1}{2} \sum_{z \sim p_{\theta}(|z|)} \log p_\theta(x|z) \\
+ \frac{1}{2} \sum_{y \sim p_{\theta}(|y|)} \log p_\theta(y|x) + \frac{1}{2} \sum_{y \sim p_{\theta}(|y|)} \log p_\theta(y|z) \\
+ \frac{1}{2} \sum_{z \sim p_{\theta}(|z|)} \log p_\theta(z|y) + \frac{1}{2} \sum_{z \sim p_{\theta}(|z|)} \log p_\theta(z|x) \\
+ \sum_{(y,z) \sim p_{\theta}(|y|,|z|)} \log p(x,y) \\
+ \sum_{(x,z) \sim p_{\theta}(|x|,|z|)} \log p(x,z) \tag{4}
\]

This lower-bound contains two types of terms. The back-translation terms, e.g.,

\[
\mathbb{E}_{y \sim p_{\theta}(|x|)} \log p_\theta(x|y),
\]

enforce that reciprocal translation models are consistent. The joint terms, e.g., \( \mathbb{E}_{(x,y) \sim p_{\theta}(|x|,|y|)} \log p(x,y) \) will vanish in our optimization procedure, as explained next.

We use the EM algorithm to maximize Eq. 4. In our setup, the E-step at iteration \( t \) amounts to computing the expectations against the conditional distributions evaluated at the current set of parameters \( \theta = \theta^{(t)} \). We approximate this by removing the expectations and replacing the random variable with the mode of its distribution i.e.,

\[
\mathbb{E}_{y \sim p_{\theta^{(t)}}(|x|)} \log p_{\theta^{(t)}}(x|y) \approx p_{\theta^{(t)}}(x|\hat{y}) \text{ where } \hat{y} = \arg \max_{y} p_{\theta^{(t)}}(y|x).
\]

In practice, this amounts to running a greedy decoding procedure for the relevant translation models.

The M-step then corresponds to choosing the \( \theta \) which maximizes the resulting terms after we perform the E-step. Notice that for this step, the last three terms in Eq. 4 no longer possess a \( \theta \) dependence, as the expectation was computed in the E-step with a dependence on \( \theta^{(t)} \). These terms can therefore be safely ignored, leaving us with only the back-translation terms. By our approximation to the E-step, these expressions become exactly the loss terms that appear in the current UNMT literature (Artetxe et al., 2019; Lample & Conneau, 2019; Song et al., 2019), see Figure 2(a) for a graphical depiction. Since computing the argmax is a difficult task, we perform a single gradient update for the M-step and define \( \theta^{(t+1)} \) inductively this way.

### 3.2. Auxiliary parallel data

We now extend our framework with an auxiliary parallel corpus (Figure 1(d)). We assume that we wish to translate from \( X \) to \( Z \), and that we have access to a parallel corpus

\[
\mathcal{D}_{x,y} \text{ that maps sentences from } X \text{ to } Y. \]

To leverage this source of data, we augment the log-likelihood \( \mathcal{L} \) as follows:

\[
\mathcal{L}_{\text{avg}}(\theta) = \mathcal{L}(\theta) + \sum_{(x,y) \in \mathcal{D}_{x,y}} \log \mathbb{E}_{z \sim \mathcal{Z}} p_\theta(x,y|z) \tag{6}
\]

Similar to how we handled the monolingual terms, we can utilize the EM algorithm to obtain an objective amenable to gradient optimization. By using the EM algorithm, we can substitute the distribution of \( \mathcal{Z} \) in Eq. 6 with the one given by \( p_\theta(z|x,y) \). The structural assumption we made in the case of monolingual data still holds: given any variable in the triplet \( (X,Y,Z) \), the remaining two are independent. Using this assumption, we can rewrite the distribution \( p_\theta(z|x,y) \) as either \( p_\theta(z|x) \) or \( p_\theta(z|y) \). Since we can decompose \( \log p_\theta(x,y|z) = \log p_\theta(x|z) + \log p_\theta(y|z) \), we can leverage both formulations with an argument analogous to the one in §3.1:

\[
\log z \sim \mathcal{Z} p_\theta(x,y|z) = \log z \sim \mathcal{Z} p_\theta(x|z)p_\theta(y|z) \\
\geq \sum_{z \sim p_\theta(|z|)} \log p_\theta(x|z) \\
+ \sum_{z \sim p_\theta(|z|)} \log p_\theta(y|z) \\
+ \sum_{z \sim p_\theta(|z|)} \log p(z) + \sum_{z \sim p_\theta(|z|)} \log p(z) \tag{7}
\]

A key feature of this lower bound is the emergence of the expressions:

\[
\mathbb{E}_{z \sim p_\theta(|z|)} \log p_\theta(x|z) \text{ and } \mathbb{E}_{z \sim p_\theta(|z|)} \log p_\theta(y|z). \tag{8}
\]

Intuitively, those terms ensure that the models can accurately translate from \( Y \) to \( Z \), then \( Z \) to \( X \) (resp. \( X \) to \( Z \), then \( Z \) to \( Y \)). Because they enforce cross-language pair consistency, we will refer to them as cross-translation terms. In contrast, the back-translation terms, e.g., Eq. 5, only enforced monolingual consistency. We provide a graphical depiction of these terms in Figure 2(b).

As in the case of monolingual data, we optimize the full likelihood with EM. During the E-step, we approximate the
expectation with evaluation of the expectant at the mode of the distribution. As with §3.1, the last two terms in Eq. 7 disappear in the $M$-step.

### 3.3. Connections with supervised and zero shot methods

So far, we have only discussed multilingual unsupervised neural machine translation setups. We now derive the other configurations of Figure 1, that is, supervised and zero-shot translation, through our framework.

**Supervised translation:** Deriving supervised translation is straightforward. Given the parallel data dataset $D_{x,y}$, we can rewrite the likelihood as:

$$
\sum_{(x,y)\in D_{x,y}} \log p_\theta(x,y) = \sum_{(x,y)\in D_{x,y}} \log p_\theta(y|x) + \log p(x)
$$

where the second term is a language model that does not depend on $\theta$.

**Zero-shot translation:** We can also connect the cross-translation term to the zero-shot MT approach from Al-Shedivat & Parikh (2019). Simplifying their setup, they consider three languages $X$, $Y$ and $Z$ with parallel data between $X$ and $Y$ as well as $X$ and $Z$. In addition to the usual cross-entropy objective, they also add agreement terms i.e. $E_{z\sim p_\theta(|x)} \log p(z|y)$ and $E_{z\sim p_\theta(|y)} \log p(z|x)$. We show that these agreement terms are operationally equivalent to the cross-translation terms i.e. Eq. 8. We first obtain the following equality by a simple application of Bayes’ theorem:

$$
\log p_\theta(y|z) = \log p_\theta(z|y) + \log p(y) - \log p(z).
$$

We then apply the expectation operation $E_{z\sim p_\theta(|x)}$ to both sides of this equation. From an optimization perspective, we are only interested in terms involving the learnable parameters so we can dispose of the term involving $\log p(y)$ on the right. Applying the same argument to $\log p_\theta(x|z)$, we obtain:

$$
E_{z\sim p_\theta(|x)} \log p_\theta(y|z) + E_{z\sim p_\theta(|y)} \log p_\theta(x|z) = E_{z\sim p_\theta(|x)} \log p_\theta(z|y) + E_{z\sim p_\theta(|y)} \log p_\theta(z|x) - E_{z\sim p_\theta(|x)} \log p(z) - E_{z\sim p_\theta(|y)} \log p(z)
$$

By adding the quantity $E_{z\sim p_\theta(|x)} \log p(z) + E_{z\sim p_\theta(|y)} \log p(z)$ to both sides of this inequality, the left-hand side becomes the lower bound introduced in the previous subsection, consisting of the cross-translations terms. The right-hand side consists of the agreement terms from Al-Shedivat & Parikh (2019). We experimented using this term instead of our cross-translation terms, but we found it to be unstable. This could be attributed to the fact that we lack $X \leftrightarrow Z$ parallel data, which is available in the setup of Al-Shedivat & Parikh (2019).

### 4. Training algorithms

We now discuss how to train the model end-to-end. We introduce a pre-training phase that we run before the EM procedure to initialize the model. Pre-training was already known to be crucial for UNMT (Lample & Conneau, 2019; Song et al., 2019). We make use of an existing method, MASS, and enrich it with the auxiliary parallel corpus if available. We refer to the EM algorithm described in §3 as fine-tuning for consistency with the literature.

#### 4.1. Pre-training

The aim of the pre-training phase is to produce an intermediate translation model $p_\theta$, to be refined during the fine-tuning step. We pre-train the model differently based on the data available to us. For monolingual data, we use the MASS objective (Song et al., 2019). The MASS objective consists of masking randomly-chosen contiguous segments of the input then reconstructing the masked portion. We refer to this operation as MASK. If we have auxiliary parallel data, we use the traditional cross-entropy translation objective. We describe the full procedure in Algorithm 1.

---

**Algorithm 1 Pre-Training**

**Input:** Datasets $\mathcal{D}$, number of steps $N$

1. Initialize $\theta \leftarrow \theta_0$
2. for step in 1, 2, 3, ..., $N$ do
   3. Choose dataset $D$ at random from $\mathcal{D}$.
   4. if $D$ consists of monolingual data then
      5. Sample batch $x$ from $D$.
      6. Masked version of $x$: $x_M \leftarrow \text{MASK}(x)$
      7. MASS Loss: $ml \leftarrow \log p_\theta(x|x_M)$
      8. Update: $\theta \leftarrow \text{optimizer_update}(ml, \theta)$
   else if $D$ consists of parallel data then
      9. Sample batch $(x, y)$ from $D$.
      10. Translation Loss: $tl \leftarrow \log p_\theta(y|x) + \log p_\theta(x|y)$
      11. Update: $\theta \leftarrow \text{optimizer_update}(ml, \theta)$
   end if
   12. end if

13. end for
We use the News Crawl datasets from WMT as our sole source of monolingual data for all the languages considered.

We used the data from years 2007-2018 for all languages except for Romanian, for which we use years 2015-2018. We ensure the monolingual data is properly labeled by using the fastText language classification tool (Joulin et al., 2016) and keep only the lines of data with the appropriate language classification. For parallel data, we used the UN Corpus (Ziemska et al., 2016) for English-Spanish, the 10^9 French-English-Gigaword corpus for the English-French and the CzEng 1.7 dataset (Bojar et al., 2016) for English-Czech. We preprocess all text by using the tools from Moses (Koehn et al., 2007), and apply the Moses tokenizer to separate the text inputs into tokens. We normalize punctuation, remove non-printing characters, and replace unicode symbols with their non-unicode equivalent. For Romanian, we also use the scripts from Sennrich4 to normalize the scripts and remove diacritics. For a given language triplet, we select 10 million lines of monolingual data from each language and use SentencePiece (Kudo & Richardson, 2018) to create vocabularies containing 64,000 tokens of each. We then remove lines with more than 100 tokens from the training set. We compute the BLEU score (Papineni et al., 2002) using the multi-bleu.pl script from Moses to be consistent with the literature (Song et al., 2019; Lample & Conneau, 2019; Li et al., 2020).

5.2. Model architectures

We use Transformers (Vaswani et al., 2017) for our translation models $p_w$ with a 6-layer encoder and decoder, a hidden size of 1024 and a 4096 feedforward filter size. We share the same encoder for all languages. Following XLM (Lample & Conneau, 2019), we use language embeddings to differentiate between the languages by adding these embeddings to each token’s embedding. Unlike XLM, we only use the language embeddings for the decoder side. We follow the same modification as done in Song et al. (2019) and modify the output transformation of each attention head in each transformer block in the decoder to be distinct for each language. Besides these modifications, we share the parameters of the decoder for every language.

5.3. Training configuration

For pre-training, we group the data into batches of 1024 examples each, where each batch consists of either monolingual data of a single language or parallel data, but not both at once. We pad sequences up to a maximum length of 100 SentencePiece tokens. During pre-training, we used the Adam optimizer (Kingma & Ba, 2015) with initial learning rate of 0.0002 and weight decay parameter of 0.01, as well as 4,000 warmup steps and a linear decay schedule for 1.2

5.1. Datasets and preprocessing

We use the News Crawl datasets from WMT as our sole source of monolingual data for all the languages considered.

5. Experiments

In this section, we discuss the details of the experiments undertaken throughout this work. We conduct experiments on the language triplets English-French-Romanian with English-French parallel data, English-Czech-German with English-Czech parallel data and English-Spanish-French with English-Spanish parallel data, with the unsupervised directions chosen solely for the purposes of comparing with previous recent work (Lample & Conneau, 2019; Song et al., 2019; Ren et al., 2019; Artetxe et al., 2019).

5.2. Model architectures

We use Transformers (Vaswani et al., 2017) for our translation models $p_w$ with a 6-layer encoder and decoder, a hidden size of 1024 and a 4096 feedforward filter size. We share the same encoder for all languages. Following XLM (Lample & Conneau, 2019), we use language embeddings to differentiate between the languages by adding these embeddings to each token's embedding. Unlike XLM, we only use the language embeddings for the decoder side. We follow the same modification as done in Song et al. (2019) and modify the output transformation of each attention head in each transformer block in the decoder to be distinct for each language. Besides these modifications, we share the parameters of the decoder for every language.

5.3. Training configuration

For pre-training, we group the data into batches of 1024 examples each, where each batch consists of either monolingual data of a single language or parallel data, but not both at once. We pad sequences up to a maximum length of 100 SentencePiece tokens. During pre-training, we used the Adam optimizer (Kingma & Ba, 2015) with initial learning rate of 0.0002 and weight decay parameter of 0.01, as well as 4,000 warmup steps and a linear decay schedule for 1.2

Table 1. BLEU scores of various models for UNMT. M-UNMT refers to our approach. The En–Fr/En–Ro and En–De/De–En directions were on newstest2014, while the En–Ro/Ro–En directions were on newstest2016. For mBART, they presented various BLEU scores for the unsupervised setup with auxiliary parallel data so we took the largest one.

million steps. For fine-tuning, we used Adagrad (Kingma & Ba, 2015) with the same learning rate and weight decay, and trained the models until convergence. We used Google Cloud TPUs for pre-training and 8 NVIDIA V100 GPUs with a batch size of 3,000 tokens per GPU for fine-tuning.

5.4. Results

We list our results in Table 1. We also include the results of six strong unsupervised baselines: (1) XLM (Lample & Conneau, 2019), a cross-lingual language model fine-tuned with back-translation; (2) MASS (Song et al., 2019), which uses the aforementioned pre-training task with back-translation during fine-tuning; (3) D2GPo (Li et al., 2020), which builds on MASS and leverages an additional regularizer by use of a data-dependent Gaussian prior; (4) The recent work of Artetxe et al. (2019) which leverages tools from statistical MT as well subword information to enrich their models; (5) the work of Ren et al. (2019) that explicitly attempts to pre-train for UNMT by building cross-lingual n-gram tables and building a new pre-training task based on them; (6) mBART (Liu et al., 2020), which is concurrent work that also examines a multilingual unsupervised setup, as well as one with auxiliary parallel data for the Romanian-English direction. We present scores for models trained with and without auxiliary data, corresponding to Figure 1(d) and Figure 1(c). We also include the results of our model after pre-training i.e. no back-translation or cross-translation objective, under the title M-UNMT (Only Pre-Train).

Our models with auxiliary data obtain better scores for almost all translation directions. Pre-training with the auxiliary data by itself gives competitive results in two of the three X–En directions. Moreover, our approach outperforms (Liu et al., 2020) which also leverages auxiliary parallel data. This suggests that our improved performance comes from both our choice of objectives and the additional data.

6. Ablations

We perform a series of ablation studies to determine which aspects of our formulation explain the improved performance. The first study probes the effect of auxiliary parallel data on the pre-training and fine-tuning phases. The next study analyzes the impact of multilinguality on fine-tuning, by examining the contribution of each loss term. The last study investigates the impact of the choice of auxiliary language. We focus on the English-Romanian pair since Romanian is low-resource, which is the most-likely setting in which UNMT would be applied.

6.1. Impact of the auxiliary data

We first examine the value provided by the inclusion of the auxiliary data, focusing on the triplet English-French-Romanian. To that end, we study four types of training configurations: (1) Our implementation of MASS (Song et al., 2019), with only English and Romanian data. (2) No auxiliary parallel data during pre-training and fine-tuning with only the multi-way back-translation objective (3) No parallel data during the pre-training phase but available during the fine-tuning phase, allowing us to leverage the cross-translation terms. (4) Auxiliary parallel data available during both the pre-training and the fine-tuning phases of training. We also include the numbers reported in the original MASS paper (Song et al., 2019) as well as the best-performing model of the WMT’16 Romanian-English news translation task (Sennrich et al., 2016) and report them in Table 2.

The results show that leveraging the auxiliary data induces superior performance, even surpassing the supervised scores of Sennrich et al. (2016). These gains can manifest in either...
We contrast the BLEU curves with the back-translation loss were removed. Finetune with our multi-way back-translation objective. To demonstrate that this is not the case, we investigate three types of fine-tuning configurations: (1) Disregard the auxiliary language and fine-tune using only back-translation with English and Romanian data as per Song et al. (2019). (2) Finetune with our multi-way back-translation objective. (3) Finetune with our multi-way back-translation objective and leverage the auxiliary parallel data through the cross-translation terms. We name these configurations BT, M-BT, and Full respectively. We plot the results of training for 100k steps in Figure 3, reporting the numbers on a modified version of the dev set from the WMT'16 Romanian-English competition where all samples with more than 100 tokens were removed.

In the En – Ro direction, the BLEU score of the Full setup dominates the score of the other approaches. Furthermore, the performance of BT decays after a few training steps. In the En – Ro direction, the BLEU score for the BT and M-BT reach a plateau about 1 point under Full. Those charts illustrate the positive effect of the cross-translation terms. We contrast the BLEU curves with the back-translation loss curves in Figure 3(c) and 3(d). We see that even that though the BT configuration achieves the lowest back-translation loss, it does not attain the largest BLEU score. This demonstrates that using back-translation for the desired (source, target) pair alone is not the best task for the fine-tuning of the auxiliary language on WMT newstest2016.
