ABSTRACT
Gas-rich galaxies are selected efficiently via quasar absorption lines. Recently, a new perspective on such absorption-selected systems has opened up by studying the molecular gas content of absorber host galaxies using ALMA CO emission line observations. Here, we present an analysis of multiple CO transitions ($L_{\text{CO}} \sim 10^9$ K km s$^{-1}$) in two $z \sim 0.5$ galaxies associated with one Lyα absorber towards J0238+1636. The CO spectral line energy distributions (CO SLEDs) of these galaxies appear distinct from that of typical star-forming galaxies at similar redshifts and is comparable with that of luminous infrared galaxies or active galactic nucleus (AGN). Indeed, these galaxies are associated with optically identified AGN activity. We infer that the CO line ratios and the $\alpha_{\text{CO}}$ conversion factor differ from the Galactic values. Our findings suggest that at least a fraction of absorption-selected systems shows interstellar medium conditions deviating from those of normal star-forming galaxies. For a robust molecular gas mass calculation, it is therefore important to construct the CO SLED. Absorption line selection identifies systems with widely distributed gas, which may preferentially select interacting galaxies, which in turn will have more excited CO SLEDs than isolated galaxies. Furthermore, we raise the question whether quasar absorbers preferentially trace galaxy overdensities.

Key words: ISM: molecules – galaxies: evolution – galaxies: formation – quasars: absorption lines.

1 INTRODUCTION
The neutral phase of the gas traced by H I is thought to be the original reservoir for star formation (SF) (Wolfe et al. 1986). Quasar absorbers associated with foreground galaxies provide a unique tool to probe this neutral gas phase down to low gas densities and at any redshift. However, the physical processes that transform H I into molecular gas and hence stars remain unconstrained. A direct probe of the fuel for SF has to come from measurements of molecular gas. Molecular Hydrogen (H$_2$) absorbers at UV wavelengths are only detected in $\approx$ 50 per cent of the H I-rich systems at low redshift (Muzahid, Srianand & Charlton 2015) and $\approx$ 15 per cent at high redshift (Noterdaeme et al. 2008). Furthermore, the median molecular fractions in absorbers with H$_2$ detections reported are low: log($f_{\text{H}_2}$) is $-1.93 \pm 0.63$ at low redshift and $-2.3 \pm 0.8$ at high redshift showing no significant evolution. These low detection rates in absorption are probably a consequence of the low sky cross-section of molecular gas compared to H I neutral gas (Zwaan & Prochaska 2006).

Progress in relating the properties of H I-rich systems to their SF has to come from identifying the galaxy counterparts to quasar absorbers. Theoretical models suggest that the true absorbers, at least those with large column density of neutral gas, are associated with galaxies (Fumagalli et al. 2011; van de Voort & Schaye 2012; Bird et al. 2014). The observational challenge of identifying the absorber host galaxy in emission has been partly overcome using high-$z$ absorbers to block the light from the background quasar in direct imaging (e.g. Fumagalli et al. 2010), using slit triangulation (e.g. Krogager et al. 2017), and due to integral field units (IFU) (e.g. Péroux et al. 2011; Fumagalli et al. 2017; Péroux et al. 2017; Rudie, Newman & Murphy 2017; Klitsch et al. 2018). Several studies report Ly α absorbers that are associated to galaxy groups instead of isolated galaxies (e.g. Bielby et al. 2016; Fumagalli et al. 2017; Péroux et al. 2017; Rahmani et al. 2017). Furthermore, Ly α absorber host galaxies exhibiting strong winds are reported in the literature (e.g. Rudie et al. 2017; Fynbo et al. 2018). Although the
number of observations of quasar absorber host galaxies is rising, the impact of selection criteria (high metalicity, etc.) and different observation techniques is unclear. Therefore, the question of exactly what population of galaxies is traced by the absorption remains.

Recently, a new perspective on relating baryons traced by cold gas and stars opened up with reports of CO rotational transitions emission in quasar absorber galaxy hosts observed with ALMA. To date 10 molecular gas-rich absorption-selected galaxies with large inferred molecular gas masses of $10^{10} - 10^{11} M_\odot$ have been analysed (Neeleman et al. 2016; Fynbo et al. 2018; Kanekar et al. 2018; Klitsch et al. 2018; Møller et al. 2018; Neeleman et al. 2018). The combination of low detection rates of H$_2$ absorption and the high molecular gas masses inferred from CO observations is a key question in this field. Here, we report the detection of two galaxies at the redshift of one Ly~$\alpha$ absorber in our (sub-)millimetre survey ALMACAL (Oteo et al. 2016). For each of these galaxies, we detect multiple CO transitions, which offers fresh clues on the molecular gas conditions of these galaxies.

## 2 SAMPLE AND REDUCTION

In this study we use ALMACAL, a (sub-)millimetre survey utilizing calibrator observations from the ALMA archive (Oteo et al. 2016). We search for CO emission lines from host galaxies of known quasar absorbers. Cross-correlating the sky positions of known absorbers detected at optical and UV wavelengths with the 749 calibrators in our ALMACAL catalogue leads to 109 positional matches. Matching the frequency coverage in ALMACAL with the redshift of the absorbers indicates a coverage of 57 absorbers in the redshift range $0.06 < z_{\text{abs}} < 3.0$ towards 26 quasars for which the frequency of at least one CO transition is observed. Here, we focus on absorber host galaxies with multiple CO emission line detections in order to study the CO excitation. We discover two new molecular gas-rich galaxies with multiple CO emission line detections at the redshift of an H~$\alpha$ absorber towards the quasar J0238+1636 at $z_{\text{abs}} = 0.524$. Additionally, we include the molecular gas-rich galaxy detected in the field of J0423−0120 ($z_{\text{abs}} = 0.633$) (Klitsch et al. 2018) in our analysis.

The retrieval of the calibrator data is described in detail in Oteo et al. (2016); the calibration and data reduction are carried out as described in Klitsch et al. (2018). The properties of the final data cubes are summarized in Table 1.

The gas properties of the absorbers, CO-detected host galaxies, and impact parameters are given in Tables 2 and 3, taken from Klitsch et al. (2018), Rao, Turnshek & Nestor 2006, Junkkarinen et al. 2004, and Burbidge et al. 1996.

The absorption towards J0238+1636 (also known as AO 0235+164) is also seen at a rest frame wavelength of 21 cm revealing a complex system of multiple absorbing clouds (Roberts et al. 1976). Two galaxies – J0238A and J0238A1 – with small impact parameters (1.1 arcsec = 7 kpc and 1.9 arcsec = 12 kpc) between the galaxy position and the quasar sight line towards J0238+1636 were identified at the absorber redshift using [O~$\text{II}$]-narrow-band imaging by Yanny, York & Gallagher (1989).

### Table 1. Summary of the ALMA observations of J0238+1636.

| Band | ang. res. | rms | vel. res | $t_{\text{int}}$ |
|------|-----------|-----|----------|-----------------|
| 4    | 0.43      | 0.18 | 36       | 0.6             |
| 6    | 0.96      | 0.24 | 25       | 5.0             |
| 7    | 0.67      | 0.14 | 20       | 1.5             |
| 7 cont. | 0.32      | 0.04 | –        | 5.1             |

For the absorber towards J04230−0120 Klitsch et al. (2018) identified a total of four galaxies at the absorber redshift using the MUSE IFU. One of these four galaxies, J0423B, is also detected in CO(2–1) and CO(3–2) emission. It is proposed that the gas seen in absorption traces either intra-group gas, or an outflow from J0423B.

The properties of the ALMA-detected galaxies are given in Table 2. Flux maps and spectra are shown in Fig. 1. The flux maps are integrated over $w_{20}$ which is also marked by the shaded area in the respective spectra. The spectra are measured using an aperture that encompasses the 3$\sigma$ contours in the moment map. The line flux is determined by integrating over $w_{20}$. We use these multiple line detections to study the CO spectral line energy distributions (CO SLEDs) of these absorption-selected galaxies (see Fig. 2).

We cannot use the Band 6 observations to measure the continuum flux of J0238A and J0238A1, because of strong residuals from the quasar continuum. In Band 7 we do not see any residuals, however, we also do not detect the two galaxies. The 3$\sigma$ upper limit assuming that the galaxies are not resolved is 0.1 mJy. We use a set of template spectra for starburst galaxies from Polletta et al. (2007) which we scale to the observed 870 $\mu$m flux converted to the rest wavelength. The fitted spectrum is then integrated in the wavelength range 8–1000 $\mu$m to obtain the total far-infrared luminosity $L_{\text{FIR}}$. This is converted to the star formation rate (SFR) using the Kennicutt (1998) relation. Based on this we derive the SFR limits reported in Table 3.

## 3 ANALYSIS

At the redshift of the absorber towards J0238+1636, we find two CO-emitting galaxies. The absorption system is likely probing the joint gas distribution of both galaxies that was also seen in emission by Chen et al. (2005). Roberts et al. (1976) reported a complex 21 cm absorption spectrum that might be due to several absorbing clouds. The main features are overplotted in Fig. 1 and coincide with J0238A and J0238A1 in velocity space.

We use the CO SLEDs shown in Fig. 2 as a diagnostic plot to distinguish between gas conditions similar to normal star-forming galaxies and more active systems. We note that the CO SLEDs are normalized to the CO(2–1) flux because the CO(1–0) emission line was not observed towards the absorption-selected galaxies. Differences in the CO SLEDs at higher J transitions will appear smaller due to this normalization.

The shape of the CO SLED determines the conversion of higher J transition line fluxes to the CO(1–0) line flux, which is used to calculate the total molecular gas mass. The CO SLEDs of J0238A and J0238A1 are clearly distinct from the CO SLED of the Milky Way or B3K galaxies. This suggests that the temperature and density in these absorption-selected galaxies are higher than in ‘normal’ star-forming galaxies. J0423B at $z = 0.633$ on the other hand shows a CO SLED only slightly steeper than that of the Milky Way and comparable with that of ‘normal’ star-forming galaxies at higher redshift ($z \sim 1.5$). The SFR of this galaxy is $50 \pm 10 M_\odot$ yr$^{-1}$ (Klitsch et al. 2018) explaining the elevated CO SLED compared to the Milky Way. Hence, the Galactic conversion factor, $\alpha_{\text{CO}} \simeq 4.6 M_\odot$ (K m s$^{-1}$pc$^2$)$^{-1}$, and the Galactic CO line ratios

Figure 1. Spectra (top, primary beam corrected) and integrated flux maps (bottom, not primary beam corrected) of the absorption-selected galaxies with multiple ALMACAL CO lines detected from the same galaxy. The figure for J0423B is reproduced from Klitsch et al. (2018). Top: The velocity of 0 km s$^{-1}$ corresponds to the redshift of the main absorption component. The dotted lines in the spectra of J0238A and J0238A1 represent the position of the second and third most prominent features in the 21 cm absorption spectrum. Bottom: The CO(3–2) emission line integrated flux maps are shown in grey-scale for all three galaxies, the contours mark the $3\sigma$, $5\sigma$, and $7\sigma$ levels of the respective maps. For each map we integrate over the coloured region in the spectra shown above. The dotted contours mark the $−3\sigma$ levels. The sight-line towards the quasar is marked by a red star. These are the first detections of multiple CO emission lines from absorption-selected galaxies enabling us to constrain the energetics of their ISM.
Figure 2. CO spectral line energy distribution of the three absorption-selected galaxies with multiple CO emission lines detected in ALMACAL. We show the CO SLED for BzK galaxies (Daddi et al. 2015), the Milky Way, QSOs, SMGs, and M82 (Ivison et al. 2011; Carilli & Walter 2013) for comparison. The CO SLEDs of two absorption-selected galaxies differ from the CO SLED of normal star-forming galaxies at the low J transitions. This suggests that the temperature and density of the molecular gas in these galaxies is higher than in normal star-forming galaxies and is more similar to high-redshift SMGs or AGN. We find hints that using the Galactic line luminosity conversion factors to derive molecular gas masses might overestimate the molecular gas masses for some absorption-selected galaxies.

We find hints that using the Galactic line luminosity conversion factors to derive molecular gas masses might overestimate the molecular gas masses for some absorption-selected galaxies.

4 DISCUSSION AND CONCLUSION

We report the detection of multiple CO emission lines from absorption-selected galaxies discovered in our ALMACAL survey. The CO SLEDs for two galaxies are more excited than those of ‘normal’ star-forming galaxies indicating that the molecular gas temperature and density are higher in these galaxies. This confirms the optical identification as BAL QSO and mix of active galactic nucleus (AGN) and starburst, respectively. These findings suggest that the Galactic CO line ratios and αCO conversion factor might not be applicable. Instead, we argue that for the absorption-selected galaxies studied here, luminous infrared galaxy-like conversion factors are more appropriate. We convert the CO line flux to LCO following the description from Solomon, Downes & Radford (1992).

To derive the molecular gas mass we convert the luminosity of the CO(2–1) transition to the CO(1–0) line luminosity. We convert the line luminosities using the median conversion factor r21 = LCO(2–1)/LCO(1–0) = 0.9 for LIRGs (Papadopoulos et al. 2012). The resulting molecular gas masses are reported in Table 3 and are 109.8–109.9 M⊙/αCO.

Comparing the LCO–LIR relation we find that J0423B is consistent with local LIRGs and that J0238A and J0238A1 are in the lower envelope of local LIRGs (Greve et al. 2014).

ACKNOWLEDGEMENTS

The authors would like to thank Helmut Dannerbauer for an interesting discussion on CO SLEDs. AK acknowledges support from the STFC grant ST/P000541/1 and Durham University. CP is grateful to the ESO and the DFG cluster of excellence ‘Origin and Structure of the Universe’ for support. IRS acknowledges support from the ERC Advanced Grant DUSTYGAL (321334), a Royal Society/Wolfson Merit Award, and STFC.
Figure 3. Left: CO(2−1) luminosity as a function of impact parameter. We show the absorption-selected galaxies presented by Kanekar et al. (2018), and the galaxies presented here. Right: CO(2−1) luminosity as a function of H I absorption column density. Errorbars are too small to be visible on these plots. We find correlation of $L_{CO}$ with the impact parameter towards the QSO sight line and an anticorrelation of $L_{CO}$ with the column density of the absorber. A fit of a linear function to the data is shown by the grey dashed line. We find the following best fits including J0423B: $L_{CO}[Kms^{-1}pc^{2}] = 1.5 \times 10^{4} b/[kpc] + 9.0 \times 10^{8}$ and $L_{CO}[Kms^{-1}pc^{2}] = -5.3 \times 10^{8} \log(N(HI)/[cm^{-2}]) + 1.2 \times 10^{9}$ and excluding J0423B: $L_{CO}[Kms^{-1}pc^{2}] = 2.7 \times 10^{7} b/[kpc] - 1.8 \times 10^{8}$ and $L_{CO}[Kms^{-1}pc^{2}] = -3.7 \times 10^{8} \log(N(HI)/[cm^{-2}]) + 8.1 \times 10^{9}$.
