Effect of operating parameters of a refining process on the solidified structure such as frequency and intensity of an alternating current has been experimentally examined by use of Sn-10mass%Pb alloy. In the refining process of a solidified structure in this manuscript, a static magnetic field and an alternating electrical current are simultaneously imposed on the local area of a metal or an alloy using copper electrodes. Concerning the intensity of the electrical current, threshold exists for the refining of the solidified structure, and the refined structure is mainly observed around the electrode in the case that the magnitude of the electrical current is around the threshold value. Imposition of the electromagnetic force in the initial stage of the solidification is crucial to obtain the refined structure in this process and the imposition in the middle stage has no refining function.

KEY WORDS: solidification; crystal refinement; electromagnetic processing of materials; local imposition of oscillation.

1. Introduction

Mechanical properties of materials such as strength, elongation and toughness highly depend upon their grain sizes, which are almost determined in a solidification process. Then the control of their solidified structure is essential for products with good mechanical properties. Heat flow control during solidification is an ordinary method to control grain sizes of solidified structures though it is difficult to apply this method to casting of large size products. Though inoculation can also refine solidified structures, it is sometimes harmful for recycling of products because of added elements.

Compression waves are attractive tools to refine solidified structures. However, non-contacting introduction of the compression waves is strongly desired for metals and alloys with high temperature melting point to avoid the difficulties such as dissolution or destruction of a transmitter.

Direct excitation of electromagnetic vibrations in a solidifying metal is another method for refining of solidified structures. Vives and Radjai et al. refined aluminum alloy structures by applying the vibration, which was excited by the simultaneous imposition of a static magnetic field and an alternating current on the whole of the alloys during solidification.

On the other hand, the authors proposed the other refining method in which a static magnetic field and an alternating current are simultaneously imposed on a local volume of a metal or an alloy. This method is useful for a large size product because of local imposition of the vibration.

In this paper, the effect of operating parameters in the refining method proposed by the authors on the solidified structure has been experimentally examined.

2. Experiment

2.1. Experimental Apparatus and Procedure

A sample of a Sn–10mass%Pb alloy was prepared by alloying a pure molten Sn (99.9%) and a pure molten Pb (99.9%). Its liquidus and eutectic temperatures are 219°C and 183°C, respectively, as shown in the phase diagram of Sn–Pb alloy (Fig. 1). A schematic view of the experimental apparatus is shown in Fig. 2. A rectangular glass vessel of length 40 mm, width 25 mm was filled with a liquid sample.
of 0.3 kg (about 40 mm depth) and was set in the bore of a super-conducting magnet. This magnet imposed an upward vertical static magnetic field of 10 T on the sample. An alternating current of 2 kHz was supplied to the sample in the particular period depending on the experimental condition through a couple of copper electrodes (thickness 2 mm × width 5 mm) inserted into the sample in the vicinity of a short wall of the vessel. Furthermore, the super-conducting magnet, the sample and the electrodes were separately supported to prevent the propagation of vibration to the sample. After the solidification of the sample, its vertical or horizontal cross-section cut parallel to the long wall was observed.

2.2. Effect of Electromagnetic Vibration on the Solidified Structure

Imposition of the electrical current started when the sample temperature became 250°C which is 31°C above the liquidus temperature, and it finished when the sample temperature became 170°C, which is 13°C below the eutectic temperature, while the magnetic field was imposed on the sample during the whole period of the solidification. Intensity of the static magnetic field and effective value of the alternating current adopted in the experiment are 10 T and 90 A, respectively.

The macrostructures of the horizontal cross-section with and without the electrical current are shown in Fig. 3. When the static magnetic field and the alternating current were simultaneously imposed on the sample, an electromagnetic vibration was excited in it. In this case, the solidified structure was refined in the whole region of the sample, while in the case without the electromagnetic vibration (without electrical current) coarse grains are observed in the whole region. That is, the electromagnetic vibration excited in the local region can refine the structure.

Temperature profiles in the samples with and without the vibration were measured at three positions. These were 20 mm above from the vessel bottom and along the long wall. The results are shown in Fig. 4. The temperature difference in the sample was less than a few Kelvins before the solidification in the samples with and without the vibration. Recalescence was clearly observed in the order of the positions B, A and C in the sample without the vibration.

On the other hand, it was not clearly observed in the sample with the vibration. That is, the electromagnetic vibration might affect nucleation in this experiment. After the recalescence, the temperature at the position B was lower than those at the other two positions in the sample without the vibration while the temperature was almost uniform in the sample with the vibration.

To confirm whether the refinement of the structure is caused or not by the electromagnetic vibration in the alloy, the electrodes shown in Fig. 5 were used, in which the lower part of the electrodes was electrically insulated and a copper block was inserted between them just above the insulated part. When these electrodes were used in the experiment, a vibrating Lorentz force was not excited in the sam-
ple but was excited in the copper block and it might propagate to the sample through the electrodes. Since the macrostructure of the sample solidified with the copper inserted electrodes is coarse as shown in Fig. 5, the electrical current flow in an alloy is crucial for refinement of a solidified structure in this process.

2.3. Effect of Frequency

Theoretical distributions of pressure change, \( p \) and velocity, \( v_x \), in a sample accompanying compression waves excited by the simultaneous imposition of a static magnetic field and an alternating current are derived\(^7\) as:

\[
v_x = V_m \frac{N \gamma}{\sqrt{1 + N^2 \gamma^4}} \times \left[ \frac{1}{\gamma \sqrt{N}} \cdot \exp \left( -\frac{x}{\delta} \right) \sin \left( -\frac{x}{\delta} + \omega t + \frac{\pi}{4} \right) \right] \\
+ \left( \frac{\cos(kx - kl)}{\sin(kl)} \right) \cos(\omega t - \phi) \\
p = P_m \frac{N}{\sqrt{1 + N^2 \gamma^4}} \times \left[ \exp \left( -\frac{x}{\delta} \right) \sin \left( -\frac{x}{\delta} + \omega t - \phi \right) \right] \\
+ \left( \frac{\sin(kx - kl)}{\sin(kl)} \right) \sin(\omega t - \phi)
\]

Fig. 5. Macrostructures using electrodes with and without Cu block.

Fig. 6. Effect of frequency on the structure. (a) Theoretical distributions of pressure and velocity, (b) macrostructure.
The symbols in these equations are summarized in the Nomenclature. The pressure change and velocity in the alloy under the experimental conditions mentioned below were calculated from the above equations and are shown in Fig. 6(a). The distributions of the pressure change and velocity depend on the frequency of the electrical current.

The effect of the frequency on the structure was examined in the experiment. The constant magnetic field of 10 T and the constant current intensity of 50 A with different frequencies of 2, 10 and 50 kHz were adopted in this experiment. The obtained macrostructures are shown in Fig. 6(b). All of the samples are refined though the theoretical distributions of the pressure change and velocity in the samples highly depend on the frequency. That is, the frequency of the alternating current does not affect the structure in this process. Compression waves are physical phenomena in which fluid motion and pressure change simultaneously propagate. If one of them has a refining function in this process, a refined structure should be observed at its loops and a coarse structure should be observed at its nodes. However, the obtained structures are almost uniformly refined. Therefore, both the fluid motion and the pressure change accompanying the compression waves might have the refining function in this process, or the other refining mechanism might exist.

### 2.4. Effect of Electrical Current Magnitude

The samples were solidified under the different magnitude of the alternating electrical current with 2 kHz frequency while the intensity of the static magnetic field was fixed at 10 T. The macrostructures are shown in Fig. 7. The structures are not refined if the current magnitude is equal to or less than 5 A while it is refined when the magnitude is 50 A and 90 A. The refining effect is observed only in the vicinity of the electrode in the case of 20 A. That is, threshold of the electrical current intensity for refinement must be exist around 20 A in this experimental condition.

The intersection numbers between grain boundaries and each diagonal of a 10 mm × 10 mm square were measured for the quantitative evaluation of the refinement. The positions of the four squares and the evaluated intersection numbers are shown in Fig. 8 as the function of the magnitude of the electrical current. The intersection number increases at the all positions as the magnitude of the electrical current increases. Refining effect is remarkable at the position C which is the nearest the electrodes. In the case of 50 A, the refinement is achieved except the position B. This means that the refining effect decreases as the increase of distance from the electrode.

### 2.5. Effect of Imposing Duration of Electrical Current on Solidified Structure

The imposing durations of the alternating current of 90 A...
adopted in this section and corresponding mass solid fractions when the electrical current was turned off are shown in Fig. 9. For the samples 1, 2, 3 and 4, the electrical current was turned on when the sample temperature became 250°C at which the alloy was liquid. For the sample 1, it was turned off when the recovery of the temperature accompanying recalescence finished, while it was turned off when the temperature reached at 210, 195 and 183°C for the samples 2, 3 and 4, respectively. For the sample 5, the current was turned on when the temperature recovered and it was turned off when the temperature decreased to 170°C. The static magnetic field of 10 T was imposed on the whole samples during solidification. The obtained macrostructures are shown in Fig. 10. Because a coarse structure is observed in the sample 5, the imposition of the electrical current in initial stage of the solidification is crucial for refinement of the structure in this process. All of the region are refined in the samples 2, 3 and 4 while some area in the sample 1 is coarse. Therefore, the imposition of the electromagnetic vibration until solid fraction reaches 0.09 is not enough but until it reaches 0.44 is enough for the refinement of the whole region of the sample in this experimental condition.

The intersection number of grain boundaries with diagonals of a 10 mm · 10 mm square for the samples 1, 2, 3, 4 and the sample without electrical current is shown in Fig. 11 as the function of the imposing time of the electrical current. The intersection numbers at the positions C and D drastically increase in the initial stage of the solidification while those at the positions A and B gradually increase, and the numbers at the all positions finally become almost the same value.

3. Conclusion

Effect of the operating parameter on the solidified structure of the Sn–Pb alloy in the electromagnetic refining process of the solidified structure in which a static magnetic field and an alternating current were locally imposed on a sample during solidification have been experimentally investigated.

The followings are main results obtained in this research.

- Frequency of the electrical current dose not affect on the solidified structure.
- Threshold intensity of the electrical current for the refining of the solidified structure exists.
- Refining effect is mainly observed around the electrode in the case that the magnitude of the electrical current is around the threshold value.
- Imposition of the electromagnetic force in the initial stage of the solidification is crucial to obtain the refined structure in this process and the imposition in the middle stage has no refining function.
