Abstract

We can compress a rectifier network while exactly preserving its underlying functionality with respect to a given input domain if some of its neurons are stable. However, current approaches to determine the stability of neurons with Rectified Linear Unit (ReLU) activations require solving or finding a good approximation to multiple discrete optimization problems. In this work, we introduce an algorithm based on solving a single optimization problem to identify all stable neurons. Our approach is on median 183 times faster than the state-of-art method on CIFAR-10, which allows us to explore exact compression on deeper ($5 \times 100$) and wider ($2 \times 800$) networks within minutes. For classifiers trained under an amount of $\ell_1$ regularization that does not worsen accuracy, we can remove up to 56% of the connections on the CIFAR-10 dataset. The code is available at the following link, https://github.com/yuxwind/ExactCompression.

1 Introduction

For the past decade, the computing requirements associated with state-of-art machine learning models have grown faster than typical hardware improvements [5]. Although those requirements are often associated with training neural networks, they also translate into larger models, which are challenging to deploy in modest computational environments, such as in mobile devices.

Meanwhile, we have learned that the expressiveness of the models associated with neural networks—when measured in terms of their number of linear regions—grows polynomially on the number of neurons and occasionally exponentially on the network depth [69, 65, 73, 81, 36, 37]. Hence, we may wonder if the pressing need for larger models could not be countered by such gains in model complexity. Namely, if we could not represent the same model using a smaller neural network. More specifically, we consider the following definition of equivalence [30, 79]:

**Definition 1.** Two neural networks $\mathcal{N}_1$ and $\mathcal{N}_2$ with associated functions $f_1 : \mathbb{R}^{n_0} \rightarrow \mathbb{R}^m$ and $f_2 : \mathbb{R}^{n_0} \rightarrow \mathbb{R}^m$ are local equivalent with respect to a domain $\mathcal{D} \subseteq \mathbb{R}^{n_0}$ if $f_1(x) = f_2(x) \forall x \in \mathcal{D}$.

There is an extensive literature on methods for compressing neural networks [18, 11], which is aimed at obtaining smaller networks that are nearly as good as the original ones. These methods generally produce networks that are not equivalent, and thus require retraining the neural network for better accuracy. They may also lead to models in which the relative accuracy for some classes is more affected than that of other classes [43].
Compressing a neural network while preserving its associated function is a relatively less explored topic, which has been commonly referred to as *lossless compression* [79, 83]. However, that term has also been used for the more general case in which the overall accuracy of the compressed network is no worse than that of the original network regardless of equivalence [95]. Hence, we regard *exact compression* as a more appropriate term when equivalence is preserved.

Exact compression has distinct benefits and challenges. On the one hand, there is no need for retraining and no risk of disproportionately affecting some classes more than others. On the other hand, optimization problems that are formulated for exact compression need to account for any valid input as opposed to relying on a sample of inputs. In this paper, we focus on how to scale such an approach to a point in which exact compression starts to become practical for certain applications.

In particular, we introduce and evaluate a faster algorithm for exact compression based on identifying all neurons with Rectified Linear Unit (ReLU) activation that have linear behavior, which are denoted as *stable*. In other words, those are the neurons for which the mapping of inputs to outputs is always characterized by a linear function, which is either the constant value 0 or the preactivation output. We can remove or merge such neurons—and even entire layers in some cases—while obtaining a smaller but equivalent neural network. Our main contributions are the following:

(i) We propose the algorithm *ISA* (Identifying Stable Activations), which is based on solving a single Mixed-Integer Linear Programming (MILP) formulation to verify the stability of all neurons of a feedforward neural network with ReLU activations. *ISA* is faster than solving MILP formulations for every neuron—either optimally [90] or approximately [79]. Compared to [79], the median improvement is of 83 times on MNIST dataset (183 times on CIFAR-10 dataset and 137 times on CIFAR-100 dataset) —and in fact greater in larger networks.

(ii) We reduce the runtime with a GPU-based preprocessing step that identifies neurons that are not stable with respect to the training set. The median improvement for that part alone is of 3.2 times on MNIST dataset.

(iii) We outline and prove the correctness of a new compression algorithm, *LEO++* (Lossless Expressiveness Optimization, as in [79]), which leverages (i) to perform all compressions once per layer instead of once per stable neuron [79].

(iv) We leverage the scalability of our approach to investigate exact compressibility on classifiers that are deeper ($5 \times 100$) and wider ($2 \times 800$) than previously studied in [79] ($2 \times 100$). We show that approximately 20% of the neurons and 40% of the connections can be removed from MNIST classifiers trained with an amount of $\ell_1$ regularization that does not worsen accuracy.

2 Related work

There are many pruning methods for sparsifying or reducing the size of neural networks by removing connections, neurons, or even layers. They are justified by the significant redundancy among parameters [23] and the better generalization bounds of compressed networks [8, 98, 87, 88].

Surveys such as [11] note that these methods are typically based on a tradeoff between model efficiency and quality: the models of compressed neural networks tend to have a comparatively lower accuracy, save some exceptions [35, 95, 87]. Nevertheless, the loss in accuracy due to compression is disproportionately distributed across classes and more severe in a fraction of them; the most impacted inputs are those that the original network could not classify well; and the overall robustness to noise or adversarial examples is diminished [43]. Furthermore, the amount of compression yielding similar performance to the original network can vary significantly depending on the task [59].

To make up for model changes and potential accuracy loss, one may rely on a three-step procedure consisting of (1) training the neural network; (2) compression; and (3) retraining. Nevertheless, the scope of compression methods is seldom restricted to the second step. For example, the compressibility of a neural network hinges on how it was trained, with regularizations such as $\ell_1$ and $\ell_2$ often used to make part of the network parameters negligible in magnitude—and hopefully in impact as well.

In fact, the two main—and recurring—themes in this topic are pruning connections when the corresponding parameters are sufficiently small [38, 66, 47, 35, 34, 57, 29, 31, 89] and when the impact of the connection on the loss function is sufficiently small [54, 39, 52, 64, 25, 96, 97, 56, 91, 92, 82]. The main issue with the first approach is that small weights may nevertheless be important,
although it is possible to empirically quantify their impact on the loss function [76]. The main issue
with the second approach is the computational cost of calculating the second-order derivatives of the
loss function in deep networks, which has lead to many approaches for approximating such values.

Overlapping with such approximations, there is a growing literature on casting neural network
compression as an optimization problem [41, 62, 1, 96, 79, 26]. Most often, these formulations aim
to minimize the impact of the compression on how the neural network performs on the training set.

Other lines of work and overlapping themes in neural network compression include combining
similar neurons [84, 63, 86, 87]; low-rank approximation, factorization, and random projection of
the weight matrices [46, 24, 51, 8, 93, 85, 91, 87, 88, 58]; and statistical tests on the relevance of a
connection to network output [95]. Many recent approaches focus on pruning at initialization instead
of after training [56, 55, 92, 89, 30] as well as on what parameters to use when these networks are
retrained [29, 61, 74].

Exact compression was only recently explored for fully-connected feedforward neural networks [79]
and graph neural networks [83]. Nevertheless, we may associate it with the literature on neural
network equivalency, which includes verifying that networks are equivalent [67, 15], identifying
operations that produce equivalent networks [42, 16, 49, 50, 72], reconstructing networks from their
outputs [3, 4, 27, 2, 75], and evaluating the effect of redundant representations on training [10, 71].

3 Setting and notation

We consider fully-connected feedforward neural networks with \( L \) hidden layers, in which we denote
\( n_l \) as the number of units—or width—of layer \( l \in \mathbb{L} := \{1, 2, \ldots, L\} \) and \( x_i^l \) as the output of the
\( i \)-th unit of layer \( l \) for \( i \in \{1, 2, \ldots, n_l\} \). For uniformity, we denote \( x_i^0 \in \mathbb{R}^{n_0} \) as the network input.

We denote the output of the \( i \)-th unit of layer \( l \) as \( y_i^l = \sigma(y_i^l) \), where the pre-activation output
\( y_i^l := w_i^l \cdot x_i^{l-1} + b_i^l \) is defined by the learned weights \( w_i^l \in \mathbb{R}^{n_l \times n_{l-1}} \) and the bias \( b_i^l \in \mathbb{R} \) of the unit as
well as the activation function \( \sigma^l : \mathbb{R} \to \mathbb{R} \) associated with layer \( l \), which is \( \sigma(u) = \max\{0, u\} \)—the
ReLU [33]. The output layer may have a different structure, such as the softmax layer [13], which is
nevertheless irrelevant for our purpose of compressing the hidden layers. For every layer \( l \in \mathbb{L} \), let \( W_i^l \) be the matrix of weights, \( W_{i}^l \) be a submatrix of \( W_i^l \) consisting of the rows in set \( \mathbb{S} \), and \( b_i^l = [b_i^1 \, b_i^2 \ldots b_i^{n_i}]^T \) be the vector of biases. Finally, let \( I_{n_l}(\mathbb{S}) \) be an \( m \times m \) diagonal matrix in which the \( i \)-th diagonal element is 1 if \( i \in \mathbb{S} \) and 0 if \( i \notin \mathbb{S} \).

4 Identifying stability for exact compression

This section explains the concept of stability and describes how MILP has been used to identify stable
neurons. If the output of neuron \( i \) in layer \( l \) is always linear on its inputs, we say that the neuron is
stable. This happens in two ways for the ReLU activation. When \( y_i^l = 0 \) for any valid input, which
implies that \( y_i^l \leq 0 \), we say that the neuron is stably inactive. When \( y_i^l = y_i^l \) for any valid input,
which implies that \( y_i^l \geq 0 \), we say that the neuron is stably active.

The qualifier valid is essential since not every input may occur in practice. If \( w_i^l \neq 0 \), there are
nonempty halfspaces on \( x_i^{l-1} \) that would make that neuron active or inactive, \( \{x_i^{l-1} : w_i^l \cdot x_i^{l-1} + b_i^l \leq
0\} \) and \( \{x_i^{l-1} : w_i^l \cdot x_i^{l-1} + b_i^l \geq 0\} \), but it is possible that valid inputs only map to one of them. For
the first layer, we only need to account for the valid inputs to the neural network. For example, the
domain of a network trained on the MNIST dataset is \( \{x^0 : x^0 \in [0, 1]^{784}\} \) [53]. For the remaining
hidden layers, we also account for the combinations of outputs that can be produced by the preceding
layers given their valid inputs and parameters. Hence, assessing stability is no longer straightforward.

We can determine if a neuron of a trained neural network is stable by solving optimization problems to
maximize and minimize its preactivation output [90]. The main decision variables in these problems
are the inputs for which the preactivation output is optimized. Consequently, there is also a decision
variable associated with the output of every neuron, in addition to other variables described below.

MILP formulation of a single neuron  For every neuron \( i \) of layer \( l \), we map every input vector
\( x_i^{l-1} \) to the corresponding output \( x_i^l \) through a set of linear constraints that also include a binary
variable \( z_i^l \) denoting if the unit is active or not, a variable for the pre-activation output \( y_i^l \), a variable
\( \chi_i^l := \max\{0, -y_i^l\} \) denoting the output of a complementary fictitious unit, and positive constants
Using MILP to determine stability  Let \( X \subset \mathbb{R}^{n_0} \) be the set of valid inputs for the neural network, which we may assume to be bounded in every direction. We can obtain the interval \( \left[ \underline{Y}_i^{l'}, \overline{Y}_i^{l'} \right] \) for the preactivation output \( y_i^{l'} \) of neuron \( i \) in layer \( l' \) by solving the following optimization problems [90]:

\[
\underline{Y}^{l'}_i := \left\{ \min \{ w_i^{l''} \cdot x_i^{l''-1} + b_i^{l''} : x^0 \in X; (1) \forall l \in [l' - 1], i \in [n_l] \} \right\}
\]

\[
\overline{Y}^{l'}_i := \left\{ \max \{ w_i^{l''} \cdot x_i^{l''-1} + b_i^{l''} : x^0 \in X; (1) \forall l \in [l' - 1], i \in [n_l] \} \right\}
\]

When \( \underline{Y}^{l'}_i \leq 0 \), then \( x_i^{l'} = 0 \) for every \( x^0 \in X \) and the neuron is stably inactive. When \( \overline{Y}^{l'}_i \geq 0 \), then \( x_i^{l'} = y_i^{l'} \) for every \( x^0 \in X \) and the neuron is stably active.

Variations of the formulations above have been proposed for diverse tasks over neural networks, such as verifying them [17], embedding their model into a broader decision-making problem [78, 9, 21], and measuring their expressiveness [81]. When stable units are identified, other optimization problems over trained neural networks become easier to solve [90]. For example, weight regularization can induce neuron stability and facilitate adversarial robustness verification [94]. There is extensive work on the properties of such formulations and methods to solve them more effectively [28, 7, 12, 80, 6].

For the purpose of identifying stable neurons, however, it is not scalable to analyze large neural networks by solving such optimization problems for every neuron [90]—or even by just approximately solving each of them to ensure that \( \overline{Y}^{l'}_i \leq 0 \) or \( \underline{Y}^{l'}_i \geq 0 \) [79].

5  A new algorithm for exact compression

Based on observations discussed in what follows (I to III), we propose a new MILP formulation to identify stable neurons (Section 5.1), means to generate feasible solutions while the formulation is solve (Section 5.2), a preprocessing step to reduce the effort to solve the formulation (Section 5.3), the resulting algorithm ISA for identifying all stable neurons at once (Section 5.4), and the revised compression algorithm LEO++ exploiting all stable neurons in each layer at once (Appendix A5).

5.1 A new MILP formulation

Consider the two observations below and their implications:

I: The overlap between optimization problems  Although previous approaches require solving many optimization problems, their formulations are all very similar: we maximize or minimize the same objective function for each neuron, the feasible set of the problems for each layer are the same, and they are contained in the feasible set of problems for the subsequent layers.

II: Proving stability is harder than disproving it  Certifying that a neuron is stable is considerably more complex than certifying that a neuron is not stable. For the former, we need to exhaustively show that all inputs lead to the neuron always being active or always being inactive, which can be achieved by solving (5) and (6) for every neuron. For the latter, we just need a pair of inputs to the neural network such that the neuron is active with one of them and inactive with the other.

Therefore, we consider the problem of finding an input that serves as a certificate of a neuron not being stable to as many neurons of unknown classification as possible. For that purpose, we define a decision variable \( p_i^l \in \{0, 1\} \) to denote if an input activates neuron \( i \) in layer \( l \). Likewise, we define a decision variable \( q_i^l \in \{0, 1\} \) to denote if an input does not activate neuron \( i \) in layer \( l \). Furthermore, we restrict the scope of the problem to state that have not been previously observed.
When we finally reach \( C \) although any random input would suffice, we have found that it is better in practice to use inputs. The runtime with a single solver call depends on the frequency with which feasible solutions are obtained. Those results imply that we can iteratively solve the new formulation as part of an algorithm to identify all stable neurons. In fact, we can determine the stability of the entire neural network with at most \( N + 1 \) times, where \( N := \sum_{i \in L} n_i \). Those results imply that we can iteratively solve the new formulation as part of an algorithm to identify all stable neurons. In fact, we can determine the stability of the entire neural network with at most \( N + 1 \) times, where \( N := \sum_{i \in L} n_i \).

Note that constraint (12) is actually not necessary. We refer to Appendix A2 for more details.

The formulation above yields an input that maximizes the number of neurons with an activation state. However, due to the relaxation of the binary domains, the input defined by the optimal solution of the LP relaxation may intuitively guide us toward maximizing the objective function. For brevity, let \( P := ([1], \ldots, [p_L]) \) and \( Q := ([1], \ldots, [Q_L]) \) characterize an instance of such optimization problem, which is formulated as follows:

\[
C(P, Q) = \max \sum_{i \in L} \left( \sum_{i \in P_i} p_i + \sum_{i \in Q_i} q_i \right)
\]

s.t.

\[
ax \in X
\]

\[
\forall l \in L, i \in [n_l] (1) - (4) \forall l \in L, i \in [n_l]
\]

\[
0 \leq p_i \leq z_i \forall l \in L, i \in [P_l]
\]

\[
0 \leq q_i \leq 1 - z_i \forall l \in L, i \in [Q_l]
\]

\[
p_i, q_i \in \{0, 1\}
\]

Note that constraint (12) is actually not necessary. We refer to Appendix A2 for more details.

The formulation above yields an input that maximizes the number of neurons with an activation state. However, due to the relaxation of the binary domains, the input defined by the optimal solution of the LP relaxation may intuitively guide us toward maximizing the objective function. For brevity, let \( P := ([1], \ldots, [p_L]) \) and \( Q := ([1], \ldots, [Q_L]) \) characterize an instance of such optimization problem, which is formulated as follows:

\[
C(P, Q) = \max \sum_{i \in L} \left( \sum_{i \in P_i} p_i + \sum_{i \in Q_i} q_i \right)
\]

s.t.

\[
ax \in X
\]

\[
\forall l \in L, i \in [n_l] (1) - (4) \forall l \in L, i \in [n_l]
\]

\[
0 \leq p_i \leq z_i \forall l \in L, i \in [P_l]
\]

\[
0 \leq q_i \leq 1 - z_i \forall l \in L, i \in [Q_l]
\]

\[
p_i, q_i \in \{0, 1\}
\]

Proposition 1. If \( C(P, Q) = 0 \), then every neuron \( i \in [P_l] \) is stably inactive and every neuron \( i \in [Q_l] \) is stably active.

Corollary 2. The stability of all neurons of a neural network can be determined by solving formulation (7)–(12) at most \( N + 1 \) times, where \( N := \sum_{i \in L} n_i \).

Those results imply that we can iteratively solve the new formulation as part of an algorithm to identify all stable neurons. In fact, we can determine the stability of the entire neural network with a single call to the MILP solver. Except for the last time that formulation (7)–(12) is solved, there is no need to solve it to optimality: any solution with a positive objective function value can be used to reduce the number of unobserved states. Hence, all that we need is to inspect every feasible solution obtained by the MILP solver and then remove the solutions in which either \( p_i = 1 \) or \( q_i = 1 \) for states that were already observed. Both of those needs can be addressed in fully-fledged MILP solvers by implementing a lazy constraint callback. We refer to Appendix A4 for more details.

When we finally reach \( C(P, Q) = 0 \), the correctness of the MILP solver serves as a certificate of the stability of those remaining neurons. The resulting algorithm is described in Section 5.4.

5.2 Inducing feasible MILP solutions

The runtime with a single solver call depends on the frequency with which feasible solutions are obtained. Although at most \( N + 1 \) optimal solutions would suffice if we were to make consecutive calls to the solver until \( C(P, Q) = 0 \), we should not expect the same from the first \( N + 1 \) feasible solutions found by the MILP solver while using the lazy constraint callback because they may not have a positive objective function value due to the \( p_i \) and \( q_i \) variables that have been fixed to 0. On top of that, obtaining a feasible solution for an MILP formulation is NP-complete [19].

III: Finding feasible solutions to MILP formulations of neural networks is easy To any valid input of the neural network there is a corresponding solution of the MILP formulation: the neural network input implies which neurons are active and what is their output when active [28]. Although any random input would suffice, we have found that it is better in practice to use inputs indirectly generated by the MILP solver. Namely, we can use the solution of the Linear Programming (LP) relaxation, which is solved at least once per branch-and-bound node. The LP relaxation is obtained from the MILP formulation by relaxing its integrality constraints. In the case of binary variables with domain \([0, 1]\), that consists of relaxing the domain of such variables to the continuous interval \([0, 1]\). We use the values of \( x^0 \) in the solution of the LP relaxation as the network input, and thus obtain a feasible MILP solution by replacing the values of the other variables—which may be fractional for the decision variables with binary domains—by the values implied by fixing \( x^0 \). However, imprecise due to the relaxation of the binary domains, the input defined by the optimal solution of the LP relaxation may intuitively guide us toward maximizing the objective function.
5.3 Preprocessing

In addition to generating feasible MILP solutions at every node of the branch-and-bound tree during the solving process, we also evaluate the training set on the trained neural network to reduce the number of states that need to be search for by the MILP solver. By using GPUs, this step can be completed in few seconds for all the experiments performed.

5.4 Identifying stable neurons

Algorithm 1, which we denote ISA (Identifying Stable Activations), identifies all stable neurons of a neural network. The prior discussion on identifying stable units leads to the steps described between lines 3 and 28. First, $P$ and $Q$ are initialized between lines 3 and 6 according to the preprocessing step described above. Next, the MILP formulation is iteratively solved between lines 7 and 28. The block between lines 8 and 9 identifies the termination criterion, which implies that the unobserved states cannot be obtained with any valid input. The block between lines 10 and 24 inspects every feasible solution to identify unobserved states and then to effectively remove the decision variables associated with those states from the objective function by adding a constraint that sets their value to 0. The block between lines 25 and 26 produces a feasible solution from a solution of the LP relaxation when the latter is produced by the MILP solver. For brevity, we assume that the block between lines 10 and 24 would leverage such solution at the next repetition of the loop.

\begin{algorithm}
\caption{ISA provably identifies all stable neurons of a neural network by iterating over the solution of a single MILP formulation to verify the occurrence of states unobserved in the training set}

\EndWhile
\Return $\{ (P^l, Q^l) \}_{i \in L}$
\end{algorithmic}
\end{algorithm}
6 Experimental results

We trained and evaluated the compressibility of classifiers for the datasets MNIST \[53\], CIFAR-10 \[48\], and CIFAR-100 \[48\] with and without \(\ell_1\) weight regularization, which is known to induce stability \[90\]. We refer to Appendix A6 for details on environment and implementation. We use the notation \(L \times n\) for the architecture of \(L\) hidden layers with \(n\) neurons each. We started at \(L = 2\) and \(n = 100\), and then doubled the width \(n\) or incremented the depth \(L\) until the majority of the runs for MNIST classifiers for any configuration timed out after 3 hours. With preliminary runs, we chose values for \(\ell_1\) which spanned from those for which accuracy is improving as \(\ell_1\) increases until those for which the accuracy starts decreasing. We trained and evaluated neural networks with 5 different random initialization seeds for each choice of \(\ell_1\). The amount of regularization used did not stabilize the entire layer. We refer to Appendix A7 for additional figures and tables with complete results.

Regularization and compression  Fig. 1 illustrates the average accuracy and number nodes that can be removed from networks according to architecture and dataset based on the amount of regularization used. When used in moderate amounts, regularization improves accuracy and very often that also coincides with enabling exact compression. We observe regularization improving accuracy in 17 of the 21 plots in Fig. 1. In 14 cases, we reduce the size of these more accurate networks. Those include all architectures for MNIST (a to g), the architecture with width 400 for CIFAR-100 (r), and all the architectures with more hidden layers for CIFAR-10 and CIFAR-100 (j, l, n, q, s, u).

Runtime improvement  Fig. 2 compares the baseline \[79\] with our approach on smaller MNIST classifiers—\(2 \times 100\), \(2 \times 200\), and \(2 \times 400\)—using \(\ell_1\) as described above. The median ratio between runtimes is 100. The overall speedup is greater in larger networks: the median runtime ratio is 77 for \(2 \times 100\), 153 for \(2 \times 200\), and 193 for \(2 \times 400\). By comparing the runtimes when not timing out with and without the preprocessing step in \(2 \times 100\), we observe a median speed up of 3.2.

Effect of regularization on compressibility  We observe more compression with more \(\ell_1\) regularization. For sufficiently large networks having the same accuracy as those trained with \(\ell_1 = 0\) on MNIST, we can remove around 20\% of the neurons and 40\% of the connections. In line with \[79\], we observe that the exact compressibility of neural networks trained with \(\ell_1 = 0\) is negligible, but also that you can have the cake and eat it too: certain choices of regularization lead to better accuracy and a smaller network. However, the cake can get very expensive as runtimes increase considerably.

Relationship between compressibility and accuracy  Fig. 3 analyzes the relationship between classifier accuracy and the number of neurons left after compression for \(2 \times 100\) classifiers. When excluding uncompressible networks with \(\ell_1 = 0\) or sufficiently small, we obtain a linear regressions with coefficient of determination \((R^2)\) of 69\% on MNIST, 91\% on CIFAR-10, and 61\% on CIFAR-100. That suggests that accuracy is a good proxy for how much a neural network can be compressed.

Motivation for exact compression  We also compared exact compression with Magnitude-based Pruning (MP), one of the most commonly used inexact methods. First, we identified all the connections that would be pruned by the removal of stably inactive neurons with our approach, which would also be harmless if identified and removed by MP. Second, we ranked all the connections based on the absolute value of their coefficients in order to identify at what pruning ratio those connections would have been removed by MP. We consistently found out across architectures of different sizes and levels of regularization that some of the pruned connections by our method would be found by MP at the 99\% percentile. In other words, even though such connections would have no impact if removed from the network, MP would only resort to removing them at very extreme levels of pruning. Furthermore, if the same pruning ratio is used with MP, on average 10\% of the total number of connections—or 18\% of the pruned connections—removed by our method would not be removed by MP.

6.1 Limitations and alternatives

Due to the use of MILP solvers, our approach is not applicable to very large networks. In what follows, we consider ways to extend our approach by lifting some or all the guarantees provided.

Inexact approach to larger networks  We evaluated the impact of using only the quick preprocessing step described in Section 5.3 to determine which neurons to remove. Note that the preprocessing step is in principle intended to identify neurons that are not stable in order to avoid spending further time on them, but we can conversely assume that all the other neurons are stable at the cost of removing more than we should. By using preprocessing alone, we identified on average 31.93\%
Figure 1: Test accuracy and nodes removed for varying amounts of $\ell_1$ regularization. The plots correspond to classifiers with different architectures on the (a)-(g) MNIST, (h)-(n) CIFAR-10, and (o)-(u) CIFAR-100 datasets. For each dataset, we keep the ranges of all the axes of the smaller plots same as the bigger plot but hide the ticks for brevity. Networks trained with $\ell_1$ regularization can be exactly compressed, even when regularization improves accuracy. In light red background, test accuracy is better than with no regularization (blue curve) and exact compression occurs (red curve).

potentially stable neurons in MNIST classifiers, 40.86% in CIFAR-10 classifiers, and 41.98% in CIFAR-100 classifiers. Among those neurons, only a few were actually not stable when evaluated with the test set. In terms of the number of not stable neurons with respect to the test set divided by the number of stable neurons with respect to the training set, we would have removed 1.16% more neurons that we should for MNIST, 0.60% for CIFAR-10, and 1.19% for CIFAR-100. We refer to Appendix A7.5 for experiments involving convolutional neural networks (CNNs).

Restricting exact compression to more likely inputs We also tested the effect of bounding the sum of all the MNIST inputs to be within the minimum and maximum observed values. In particular, we have constrained the sum of all inputs to be within the interval [15, 320] instead of [0, 784]. We believed that this approach would be preferable to constraining the value of individual inputs, since that would have affected the output upon rotation and translation. Note that this constraint is equivalent to imposing a prior on the number of foreground pixels on the digits to be within a range.
Global priors that jointly act on all the pixels have been used in computer vision in the pre-deep learning era, e.g., [22]. By restricting the analysis to the cases in which the time limit has not been exceeded either before or after the change, we obtained a better runtime in 69.6% of the cases and the runtime geometric mean went down by 17.7%.

7 Conclusion

This paper outlined the potential for exact compression of neural networks and presented an approach that makes it practical for sizes that are large enough for many applications. To the best of our knowledge, our approach is the state-of-the-art for optimization-based exact compression. Our performance improvements come from insights about the MILP formulations associated with optimization problems over neural networks, which have many other applications besides exact compression. Most notably, such formulations are also used for network verification [14, 60, 77].

Societal Impact Large models are resource-intensive for both training as well as inference. In contrast to approximate methods, our exact model compression algorithms can help deep learning practitioners to save computational time and resources without worrying about any loss in performance. That helps preventing the documented side effect of disproportionally degrading performance for some classes more than for other classes when the indicator of a successful compression is the overall performance, which could also lead to fairness issues [43, 68, 44].

A1 Description of MILP formulation for a ReLU activation

The formulation below is used to identify inputs for which a given output or activation pattern can be achieved. The decision variables include (i) the vector $x^0$ associated with the input of the neural network; (ii) the vector $y^i$ associated with the preactivation output of each hidden layer of the neural network; (iii) the vector $x^l$ associated with the output of each hidden layer of the neural network; (iv) the vector $\chi^l$ associated with the complementary output of each hidden layer of the neural network; and (v) the binary vector $z^l$ defining which neurons are active or not in each hidden layer of the neural network. The vector of weights $w^l_i$ and the bias $b^l_i$ associated with each neuron as well as the constants $M^l_i$ and $\mu^l_i$ are coefficients of the formulation. The constraints are as follows:

\begin{align}
  w^l_i \cdot x^{l-1} + b^l_i &= y^l_i \\
  y^l_i &= x^l_i - \chi^l_i \\
  x^l_i &\leq M^l_i z^l_i \\
  \chi^l_i &\leq \mu^l_i (1 - z^l_i) \\
  x^l_i &\geq 0 \\
  \chi^l_i &\geq 0 \\
  z^l_i &\in \{0, 1\}
\end{align}

Constraint (13) matches the layer input $x^{l-1}$ with the neuron preactivation output $y^l_i$. We then use the binary variable $z^l_i$ to match $y^l_i$ with the neuron output with either $x^l_i$ or 0. When $z^l_i = 1$, constraints (16) and (18) imply that $\chi^l_i = 0$, and thus $x^l_i = y^l_i$ due to constraint (14). That only happens if $y^l_i \geq 0$ due to constraint (17). When $z^l_i = 0$, constraints (15) and (17) imply that $x^l_i = 0$, and thus $\chi^l_i = -y^l_i$. That only happens if $y^l_i \leq 0$ due to constraint (18).

A2 On dropping constraint (12)

We avoid explicitly enforcing that variables $p^l_i$ and $q^l_i$ are binary by leveraging that $z^l_i$ is binary. Constraint (10) implies that $p^l_i \in [0, 1]$ and $p^l_i \neq 0$ only if $z^l_i = 1$. In turn, if $z^l_i = 1$, then we can assume $p^l_i = 1$ by optimality since the objective function (7) maximizes the sum of those variables and no other constraint limits its value. Likewise, constraint (11) implies that $q^l_i \in [0, 1]$ and $q^l_i \neq 0$ only if $z^l_i = 0$. In turn, if $z^l_i = 0$, then likewise we can assume $q^l_i = 1$ by optimality since the objective function (7) maximizes the sum of those variables and no other constraint limits its value. Reducing the number of binary variables is widely regarded as a good practice to make MILP formulations easier to solve.

A3 Proofs from Section 5.1

Proposition 1. If $C(P, Q) = 0$, then every neuron $i \in P^l$ is stably inactive and every neuron $i \in Q^l$ is stably active.

Proof. Constraint (10) is the only upper bound on $p^l_i$ besides constraint (12). Hence, if there is any solution $(\bar{x}, \bar{z}, \bar{p}, \bar{q})$ of (9)–(12) in which $\bar{z}^l_i = 1$ for some $i \in P^l$, $l \in \mathbb{L}$, then either $\bar{p}^l_i = 1$ or there is another solution $(\tilde{x}, \tilde{z}, \tilde{p}, \tilde{q})$ in which $\tilde{p}^l_i = 1$ and all other variables have the same value.

Likewise, constraint (10) is the only upper bound on $q^l_i$ besides constraint (12). Hence, if there is any solution $(\bar{x}, \bar{z}, \bar{p}, \bar{q})$ of (9)–(12) in which $\bar{z}^l_i = 0$ for some $i \in P^l$, $l \in \mathbb{L}$, then either $\bar{q}^l_i = 1$ or there is another solution $(\tilde{x}, \tilde{z}, \tilde{p}, \tilde{q})$ in which $\tilde{q}^l_i = 1$ and all other variables have the same value.
Algorithm 2, which we denote as LEO++, (Lossless Expressiveness Optimization, as in [79]), leverages neuron stability for exactly compressing neural networks. We describe next each form of compression contained in the algorithm. For ease of explanation, they are in reverse order of appearance. These compression operations are the same as in [79], but performed once per layer instead of once per neuron. In comparison to the original algorithm LEO, the order of the operations is such that (i) neurons are not removed or merged if the entire layer is going to be folded; and (ii) special cases such as a neuron with weight vector $u_r = 0$ do not need to be considered apart. For the most elaborate operations, we prove their correctness when applied to the entire layer.

**Removal of stably inactive neurons** This operation is performed in line 25. Since the output of stably inactive neurons is always 0, we remove those neurons without affecting subsequent computations. The case in which an entire layer is stably inactive is considered separately.

**Merging of stably active neurons** This operation is performed between lines 12 and 24. We use the following results to show how stably active neurons can be merged.

**Proposition 3.** Let $S$ be a set of stably active neurons in layer $l$. If $r := \text{rank}(W^l_S) < |S|$ and let $T \subset S$ be a subset of those neurons for which $\text{rank}(W^l_T) = r$, then the output of the neurons in $S \setminus T$ is an affine function on the output of the neurons in $T$.
Algorithm 2 LED++ performs exact compression of a neural network with a single operation per layer

\begin{algorithm}
\begin{algorithmic}[1]
\STATE {\textbf{Input:}} neural network \( \left( L, \{ (n_l, W^l, b^l) \}_{l \in L} \right) \) and stable neurons \( \left( \{ (P^l, Q^l) \}_{l \in L} \right) \)
\FOR {\( l \leftarrow 1 \) \textbf{to} \( L \)} \Comment{Loops over all hidden layers}
  \IF {\( |P^l| = n_l \)} \Comment{Entire layer is stably inactive}
    \STATE find output \( \overline{X}^l \) for an arbitrary input \( \overline{X}^0 \in X \)
    \STATE remove all layers except \( L \), which becomes 1
    \STATE \( W^l \leftarrow 0 \) and \( b^l \leftarrow \overline{X}^L \)
    \STATE \textbf{break} \Comment{All hidden layers were collapsed}
  \ELSE IF {\( |P^l| + |Q^l| = n_l \) and \( l < L \)} \Comment{Entire layer is stable, but not inactive}
    \STATE \( W^{l+1} \leftarrow W^{l+1}I_{n_l(Q^l)}W^l \) and \( b^{l+1} \leftarrow W^{l+1}I_{n_l(Q^l)}b^l + b^{l+1} \)
    \STATE remove layer \( l \)
    \STATE \textbf{if} \( l < L \)
      \STATE \( r \leftarrow \text{rank} \left( W^l_{Q^l} \right) \)
      \IF {\( r < |Q^l| \) and \( l < L \)}
        \STATE find \( \overline{Q} \subset Q^l \) such that \( r = |\overline{Q}| = \text{rank} \left( W^l_{\overline{Q}} \right) \)
        \FOR {\( i \in Q^l \setminus \overline{Q} \)}
          \STATE find \( \{ \alpha^l_j \}_{j \in \overline{Q}} \) such that \( w^l_i = \sum_{j \in \overline{Q}} \alpha^l_j w^l_j \)
        \ENDFOR
        \FOR {\( k \leftarrow 1 \) \textbf{to} \( n_{l+1} \)}
          \FOR {\( j \in \overline{Q} \)}
            \STATE \( w^{l+1}_{k j} \leftarrow w^{l+1}_{k j} + \sum_{i \in \overline{Q}} \alpha^l_j w^{l+1}_{k i} \)
          \ENDFOR
          \STATE \( b^{l+1}_k \leftarrow b^{l+1}_k + \sum_{i \in \overline{Q}} \alpha^l_j b^{l+1}_j \)
        \ENDFOR
        \STATE remove from layer \( l \) every neuron \( i \in Q^l \setminus \overline{Q} \)
        \STATE remove from layer \( l \) every neuron \( i \in P^l \)
      \ENDIF
  \ENDIF
\ENDFOR
\end{algorithmic}
\end{algorithm}

\textit{Proof.} For every \( i \in S \setminus T \), there is a vector \( \alpha^i \in \mathbb{R}^r \) such that \( w^l_i = \sum_{j \in T} \alpha^l_j w^l_j \). Since \( x^l_i = w^l_i \cdot x^{l-1} + b^l_i \) for every \( i \in S \) because all neurons in \( S \) are stably active, then for every \( i \in S \setminus T \) it follows that \( x^l_i = \sum_{j \in T} \alpha^l_j w^l_j \cdot x^{l-1} + b^l_i = \sum_{j \in T} \alpha^l_j (w^l_j \cdot x^{l-1} + b^l_j) + (b^l_i - \sum_{j \in T} \alpha^l_j b^l_j) = \sum_{j \in T} \alpha^l_j x^l_j + (b^l_i - \sum_{j \in T} \alpha^l_j b^l_j) \). \( \square \)

\textbf{Corollary 4.} If \( S, T, \) and \( l \) are such as in Proposition 3, then the pre-activation output of the neurons in layer \( l + 1 \) is an affine function on the outputs of all neurons from layer \( l \) with exception of the neurons in \( T \).

\textit{Proof.} Let \( U := \{ 1, \ldots, n_l \} \setminus S \). The pre-activation output of every neuron \( i \) in layer \( l + 1 \) is given by
\[
\begin{align*}
  y^{l+1}_i &= \sum_{j \in U \cup S} w^{l+1}_{ij} x^l_j + b^{l+1}_i = \sum_{j \in U \cup T} w^{l+1}_{ij} x^l_j + \sum_{j \in S \setminus T} w^{l+1}_{ij} \left( \sum_{k \in T} \alpha^l_k x^l_k + \left( b^l_j - \sum_{k \in T} \alpha^l_k b^l_k \right) \right) + \\
  b^{l+1}_i &= \sum_{j \in U} w^{l+1}_{ij} x^l_j + \sum_{j \in T} \left( w^{l+1}_{ij} + \sum_{k \in S \setminus T} \alpha^l_k w^{l+1}_{kj} \right) x^l_j + \left( b^{l+1}_i + \sum_{j \in S \setminus T} w^{l+1}_{ij} \left( b^l_j - \sum_{k \in T} \alpha^l_k b^l_k \right) \right).
\end{align*}
\] \( \square \)

In Algorithm 2, we use relationships implied by the proof of Corollary 4 with \( S = Q^l \) and \( T = \overline{Q} \) to merge stably active neurons. By adjusting the biases of the neurons in the next layer as well as the weights connecting every neuron in \( \overline{Q} \) with the neurons in the next layer, we assign a weight of 0 to
the connections between every neuron in $Q_l^i \setminus Q_l$ and the neurons in the next layer. Hence, we simply remove all neurons in $Q_l^i \setminus Q_l$ after adjusting those network parameters.

The case in which an entire layer is stably active—either before any compression is applied or once stably inactive neurons are removed—is also considered separately.

**Folding of stable layers** This operation is performed between lines 8 and 10. We use the following results to show that stable layers can be folded in a single step.

**Proposition 5.** If all the neurons of layer $l \in L \setminus \{1\}$ are stably active, then the pre-activation output of layer $l + 1$ is an affine function on the inputs of layer $l$.

**Proof.** Since $x_l^i = W_l^i x_{l-1}^i + b_l^i$, then $y_{l+1}^{i+1} = W_{l+1}^i x_l^i + b_{l+1}^i = W_{l+1}^i W_l^i x_{l-1}^i + (W_{l+1}^i b_l^i + b_{l+1}^i)$. $\square$

**Corollary 6.** If all neurons of layer $l \in L \setminus \{1\}$ are stable, then the pre-activation output of layer $l + 1$ is an affine function on the inputs of layer $l$.

**Proof.** Let $S$ be the set of stably active neurons in layer $l$. If $|S| < n_l$, the identity $x_l^i = W_l^i x_{l-1}^i + b_l^i$ still holds if the bias and the weights of all the connections of the neurons not in $S$ with the neurons in the next layer are 0. More generally, we can thus obtain an equivalent neural network if $W_l^i$ and $b_l^i$ are both premultiplied by $I_{n_l}(S)$ since that only would change the weights and biases associated with the neurons not in $S$ to 0. Hence, the identity $x_l^i = I_{n_l}(S)(W_l^i x_{l-1}^i + b_l^i)$ always holds if all neurons in layer $l$ are stable, which implies that $y_{l+1}^{i+1} = W_{l+1}^i I_{n_l}(S) W_l^i x_{l-1}^i + (W_{l+1}^i I_{n_l}(S)b_l^i + b_{l+1}^i)$. $\square$

In Algorithm 2, we use relationships implied by the proof of Corollary 6 with $S = Q_l^i$ to fold stable layers. By adjusting the biases and the weights of layer $l + 1$, that layer directly uses the outputs from layer $l - 1$.

Although the steps above would apply if a layer is stably inactive, that case deserves separate consideration.

**Collapse of a network with stably inactive layers** This operation is performed between lines 3 and 7. If layer $l \in L$ are stably inactive, then $x_l^i = 0$ for any input $x_0^i \in X$ and thus the value of $x_L^i$ is constant. Hence, we collapse layers 1 to $L - 1$ by making the output of the remaining layer constant and equal to such value of $x_L^i$.

A5.1 On the complexity of the new algorithm

While LEO++ requires solving fewer optimization problems than LEO [79], the dependence on solving a single NP-hard problem—such as MILP formulations in general—implies an exponential worst-case complexity. Nevertheless, the progress of MILP in the past decades makes it possible to solve considerably large problems with state-of-art MILP solvers. In that context, the computational experiments are a more appropriate indicator of performance improvements than complexity considerations.
A6 Implementation details

We now provide additional experimental results evaluating our proposed method and the baseline.

**Architecture and Loss**  We implemented the fully connected architectures in PyTorch [70]. All the networks have ReLU activations but have varying number of layers and width. For the classifiers, we pass the output through a softmax layer and use negative log-likelihood loss as the loss function. For the autoencoders, we use MSE loss as the loss function.

**Datasets and Splits**  We keep the output units at 10 and 784 for the MNIST dataset [53] classifiers and autoencoders, respectively. We keep the output units at 10 and 100 for the CIFAR-10 and the CIFAR-100 dataset [48] classifiers, respectively. We use the standard train-validation data splits of each of the datasets available in PyTorch.

**Data Augmentation**  We do not do any data augmentation of training images of the MNIST dataset as in [79] for a fair comparison. We carry out the standard data augmentation of training images of the CIFAR-10 and CIFAR-100 datasets: horizontal flipping with probability 0.5, random rotation in the range between $(-10^\circ, 10^\circ)$, random scaling in the range $(0.8, 1.2)$, random shear parallel to the x axis in the range $(-10, 10)$, and scaling the brightness, contrast, saturation and hue by a random factor in the range $(0.8, 1.2)$.

**Optimization**  Training proceeds from scratch for 120 epochs and starts with learning rate of 0.01, which is decayed by a factor of 0.1 after every 50 epochs as in [79]. We use SGD with momentum optimizer, with a momentum of 0.9 and batch size 128 as in [79]. Unless stated otherwise, we use $\ell_1$ regularization. We keep the weight decay at 0 unless otherwise stated. We consider the model saved in the last epoch as our final model.

**MILP Solver**  We solve the MILP formulations using Gurobi 9.1.0 through gurobipy [32]. We calculate the value of the positive constants $M_l^i$ and $\mu_l^i$ for each neuron with an upper bound of on the values of $x_l^i$ and $\chi_l^i$ through interval arithmetic by taking element-wise maxima [17].

**Initialization**  We initialize the weights of the network with the Kaiming initialization [40] and the biases to zero with different random seeds for each training. We train every setting 5 times, and get the stably active and inactive neurons with the proposed approach to prune the network for each run. We omit from the summaries the runs which resulted in a time out. We keep the timeout to 3 hours.

**Hardware**  We ran the classifier experiments on a machine with Intel Core i7-4790 CPU @ 3.60 GHz processor, 32 GB of RAM, and one 4 GB Nvidia GeForce GTX 970 GPU. The autoencoder experiments were run on a machine with 40 Intel Xeon E5-2640 CPU @ 2.40 GHz processors, 126 GB of RAM, and one 12 GB Nvidia Titan Xp GPU.
A7 Additional experiments and results

A7.1 MNIST Classifiers

Relationship between Runtime and Regularization  Tab. 1 and Tab. 2 show the runtime achieved by the proposed method at different $\ell_1$ regularization on MNIST classifiers.

Figure 4: **MNIST Classifiers: Comparison of runtimes** for proposed method (solid) and baseline (dashed) with the strength of regularization to identify stable neurons: (a) with increasing width (b) with increasing depth. We report the average and the standard deviation of the runtime of models with five different initialization for each regularization. Note that the y-axis is in the log scale. The median speedup is **81 times**.

Figure 5: **Relationship between size of compressed neural network and accuracy on 2 × 100 MNIST classifiers.** The coefficient of determination ($R^2$) for the linear regression obtained for accuracy based on neurons left for compressible networks is **69%**.
A7.2 MNIST Autoencoders

For the autoencoders, we use the notation \( n_1 \mid n_2 \mid n_3 \) for the architecture of 3 hidden layers with \( n_1, n_2, \) and \( n_3 \) neurons. The output layer has the same size as the input, 784, and uses ReLU activation. Starting with the architecture 100 \( \mid 10 \mid 100 \), we evaluated changes to the bottleneck width \( n_2 \) as well as to the width of the other two layers. First, we changed the bottleneck width to \( n_2 = 25 \) and \( n_2 = 50 \). Second, we changed the width of the other layers to \( n_1, n_3 = 50, n_1, n_3 = 200, \) and \( n_1, n_3 = 400 \) while keeping \( n_2 = 10 \). For each architecture, we trained and evaluated neural networks with 5 different random initialization seeds using \( \ell_1 = 0, \ell_1 = 0.00002, \) and \( \ell_1 = 0.0002 \).

**Relationship between Runtime and Regularization**

Table 3 reports the runtime to identify stable neurons and the proportion of neurons—as well as the corresponding connections—that can be removed due to stability in each case on MNIST Autoencoders.

With the largest amount of regularization, we notice that the runtimes are considerably smaller and most of the network can be removed while the loss during training only doubles in comparison to using zero or a moderate amount of regularization. In fact, the only neurons that are not stable in such case are in the first layer, whereas between 3 and 4 out of the 5 neural networks trained for each architecture have all hidden layers completely stable. By also evaluating the stability of the output layer, we identified a few cases in which the output layer is entirely stable. While we have not explicitly explored that possibility in the proposed algorithm, the implication for such case is that the neural network can be reduced to a linear function on the domain of interest. With autoencoders, we observed that this can happen when the regularization during training no more than doubles the loss, and that we can evaluate if that happens within seconds: the runtime when the stability of the output layer is tested is 1 seconds on average and never more than 25 seconds.

**Runtime Comparison with SoTA**

Fig. 6 shows the difference in runtimes between our approach and the baseline [79] for higher regularization, fixed \( n_2 = 10 \), and varying but equal values for \( n_1 \) and \( n_3 \) on the MNIST Autoencoders. We observe that the new method presents a median gain of 159 times in running time, which increases with the width of the non-bottleneck layers.

### Table 3: MNIST Autoencoders: Compression results with varying architectures and levels of regularization.

| Architecture | \( \ell_1 \) | Loss | Compression Runtime (s) | \% Removed Neurons | % Removed Connections | Timed Out |

Figure 7: **CIFAR-10 Classifiers: Comparison of runtimes** for proposed method (solid) and baseline (dashed) with the strength of regularization to identify stable neurons: (a) with increasing width (b) with increasing depth. We report the average and the standard deviation of the runtime of models with five different initialization for each regularization. Note that the y-axis is in the log scale. The median speedup is 183 times.

Figure 8: **Relationship between size of compressed neural network and accuracy on 2 × 100 CIFAR-10 classifiers.** The coefficient of determination ($R^2$) for the linear regression obtained for accuracy based on neurons left for compressible networks is 91%.
A7.4 CIFAR-100 Classifiers

Relationship between Runtime and Regularization Tab. 6 and Tab. 7 show the runtime achieved by the proposed method at different $\ell_1$ regularization on the CIFAR-100 classifiers.

Table 6: CIFAR100 Classifiers: Compression results with fixed width and varying depth.

| ARCH | $\ell_1$ | ACCURACY (%) | COMPRESSION RUNTIME (s) | % REMOVED NEURONS | % REMOVED CONNECTIONS | TIMED OUT |

Figure 9: **CIFAR-100 Classifiers: Comparison of runtimes** for proposed method (solid) and baseline (dashed) with the strength of regularization to identify stable neurons: (a) with increasing width (b) with increasing depth. We report the average and the standard deviation of the runtime of models with five different initialization for each regularization. Note that the y-axis is in the log scale. The median speedup is 137 times.

Figure 10: **Relationship between size of compressed neural network and accuracy** on 2 × 100 CIFAR-100 classifiers. The coefficient of determination ($R^2$) for the linear regression obtained for accuracy based on neurons left for compressible networks is 61%.
A7.5 Extensions to CNNs: CIFAR-10 LeNet Classifiers

We also test our approach with the LeNet [53] architecture on CIFAR-10 using the preprocessing step as a predictor of neuron stability to make it more scalable. We note that in this case we would only use our method as a sparsification technique to mask stably inactive zeros due to parameter sharing. When no regularization is used and the test accuracy on CIFAR-10 is around 68.7% before pruning, we find that an average of 10.98% of the stably inactive neurons can be masked as 0. With an $\ell_1$ regularization of 0.000175, test accuracy on CIFAR-10 is around 70.02% before pruning while an average of 11.86% of the stably inactive neurons can be masked as 0. In comparison to the case of MLPs, we observe more variability on the number of stable neurons across networks trained with the same amount of regularization, which we believe is due to weight sharing. Similar to the case of MLPs, the proportion of neurons that are stable in the training set but not stable in the test set is relatively small: 1.06% on average. Moreover, we observe that pruning those extra neurons has a zero net effect on accuracy for regularization values in the interval $[0, 0.0003]$.

On a final note, we emphasize that masking 10% of the neurons is more strict than masking 10% of the parameters as done for lossy compression. Furthermore, masking 10% of the neurons does not prevent someone from sparsifying the CNN even further: our method merely identifies a set of neurons—and corresponding parameters—that can be ignored for not being relevant. We believe that our method could be used in conjunction with conventional sparsification techniques in order to decompose the pruning operations of those into a lossless and a lossy component.

A8 Extensions to Data and Batch Normalization

Normalization layers, specially Batch Normalization [45], are present in almost every modern neural network [40]. We now show how to extend our approach to these layers.

Data Normalization

Data normalization transforms the input $x$ as

$$\text{Norm}(x) = \frac{x - \mu}{\sigma},$$

where $(\mu, \sigma)$ correspond to the mean and standard deviation of the data, respectively.

Since, we assume the image pixels to lie in the range $[0, 1]$, the data normalization layer brings the image pixels in the range $[-\mu/\sigma, 1-\mu/\sigma]$. Thus, we incorporate data normalization in our approach by adjusting the input bounds using the mean and standard deviation parameters. Hence, we replace the constraint $x \in [0, 1]$ with the new constraint $x \in [-\mu/\sigma, 1-\mu/\sigma]$.

Batch Normalization

Batch Normalization (BN) [45] corresponds to applying the affine transformation to the input $x$ as

$$\text{BN}(x) = \gamma \left( \frac{x - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} \right) + \beta,$$

where $(\mu_B, \sigma_B^2)$ are the mean and variance (the mini-batch statistics) of the data, $(\gamma, \beta)$ are the trainable parameters, and $\epsilon$ is a small constant to avoid division by zero.

For lossless compression, we run the MILP solver after the training of the neural network completes. Thus, BN mini-batch statistics are frozen (do not update) while running MILP, and BN only serves to scale the layer input. If the layer input before the BN layer is in the range $[h_{\min}, h_{\max}]$, the BN layer brings these input in the range $\gamma \left( \frac{h_{\min} - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} \right) + \beta, \gamma \left( \frac{h_{\max} - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} \right) + \beta$. Thus, BN does not introduce any extra constraint for the MILP formulation.

We end this discussion on a final note. Although BN in inference does an affine transform of the input, BN in inference is different from the fully connected layer. BN in inference transforms the inputs individually without taking contributions from other inputs into account. On the other hand, a fully connected layer does an affine transform while taking the contributions of all inputs into account.
