The Astrin-SKAP complex reduces friction at the kinetochore-microtubule interface

Highlights

- SKAP increases kinetochore motility during mammalian metaphase
- SKAP decreases friction at the kinetochore-microtubule interface, lubricating it
- SKAP increases kinetochore-microtubule interface’s dynamics and force responsiveness
- Reducing interface friction independently of grip may be key to robust attachments

SUMMARY

The kinetochore links chromosomes to spindle microtubules to drive chromosome segregation at cell division. While we know nearly all mammalian kinetochore proteins, how these give rise to the strong yet dynamic microtubule attachments required for function remains poorly understood. Here, we focus on the Astrin-SKAP complex, which localizes to bioriented kinetochores and is essential for chromosome segregation but whose mechanical role is unclear. Live imaging reveals that SKAP depletion dampens the movement and decreases the coordination of metaphase sister kinetochores and increases the tension between them. Using laser ablation to isolate kinetochores bound to polymerizing versus depolymerizing microtubules, we show that without SKAP, kinetochores move slower on both polymerizing and depolymerizing microtubules and that more force is needed to rescue microtubules to polymerize. Thus, in contrast to the previously described kinetochore proteins that increase the grip on microtubules under force, Astrin-SKAP reduces the grip, increasing attachment dynamics and force responsiveness and reducing friction. Together, our findings suggest a model where the Astrin-SKAP complex effectively “lubricates” correct, bioriented attachments to help preserve them.

INTRODUCTION

The kinetochore links each chromosome to spindle microtubules at cell division, transmitting spindle forces to move chromosomes. To perform its function, the kinetochore must not only bind microtubules strongly enough to resist cellular forces but also slide on them to move and segregate chromosomes. Although we now have a detailed map of mammalian kinetochore components and are uncovering their structure, biochemistry, and biophysics, how these components together give rise to the mechanics of the kinetochore-microtubule interface remains poorly understood. Indeed, we cannot as yet reconstitute mammalian kinetochores or the microtubule bundles they bind to in vitro, and applying precise mechanical perturbations to mammalian kinetochores remains challenging in vivo. How mammalian kinetochore-microtubule attachments can be robust and strong yet dynamic remains an open question. Answering this question is central to understanding how cells accurately segregate their chromosomes.

To perform its function, the kinetochore-microtubule interface both generates and responds to force. In mammalian cells, the kinetochores bind to the 15–25 microtubules that form a kinetochore-fiber (k-fiber)1,2 and that both polymerize and depolymerize. When sister kinetochores oscillate together at metaphase, active (energy-consuming) force generation from the microtubule depolymerization at the “front” kinetochore (moving toward the pole) largely drives the movement of the pair; in turn, passive, frictional force at the “back” kinetochore (moving away from the pole) is generated as the kinetochore proteins slide on microtubules and oppose movement (Figure 1A).3–8 The kinetochore-microtubule interface also responds to force. For example, force coordinates microtubule dynamics at both sister kinetochores as chromosomes move7,9,10 and helps maintain chromosomes in the spindle center through spatially regulated polar ejection forces.11,12 Key to the interface’s ability to generate and respond to force is that it is dynamic: this allows kinetochore mobility on microtubules and microtubule growth and shrinkage, and as such perturbing microtubule dynamics causes segregation defects.13 While we now know different kinetochore molecules that generate force and increase grip at the microtubule interface,14–21 the mechanisms that make this interface dynamic and able to respond to force despite this grip remain poorly defined.

Ndc80 and Ska kinetochore complexes play central roles in microtubule attachment in mammalian cells. The Ndc80 complex is essential to the formation of kinetochore-microtubule attachments in vivo14 and directly binds microtubules, forming

load-bearing attachments in vitro. During mitosis, progressive dephosphorylation of the Ndc80 component Hec1 increases its microtubule affinity, load-bearing ability, and grip on polymerizing microtubules. Thus, Ndc80 binds more stably to microtubules as attachments mature, with one phosphorylation site (S69 on protein Hec1) maintaining basal interface dynamics. In turn, the Ska complex is essential for proper chromosome alignment and mitotic progression but is only loaded at kinetochores once they biorient and in an Ndc80-dependent manner. In vivo, Ska increases attachment stability to depolymerizing microtubules under force. In vitro, Ska directly binds microtubules and increases Ndc80’s affinity for microtubules and microtubule tracking and load-bearing ability on depolymerizing microtubules. Thus, Ska is thought to be a “locking” factor increasing the grip on microtubules and stabilizing mature attachments. In addition to Ndc80 and Ska, the Astrin-SKAP (SKAP for short hereafter) complex has been proposed to contribute to microtubule attachment. Like Ska, SKAP is essential for chromosome alignment and mitotic progression and is only loaded at bioriented kinetochores in a Ndc80-dependent manner. Strikingly, similar to Ndc80 dephosphorylation, SKAP depletion decreases k-fiber poleward flux, suggesting that SKAP’s presence at the kinetochore may not increase the grip on microtubules. Yet SKAP directly interacts with microtubules in vitro, synergistically with Ndc80. Similar to Ndc80 and Ska, mutations in SKAP expression are highly frequent in some cancers and increase aneuploidy. Yet SKAP’s mechanical role at the kinetochore-microtubule interface, if any, is not known. More broadly, whether all microtubule-binding kinetochore proteins increase microtubule grip, as Ndc80 and Ska, mutations or changes in SKAP expression are highly frequent in some cancers and increase aneuploidy. Yet SKAP’s mechanical role at the kinetochore-microtubule interface, if any, is not known. More broadly, whether all microtubule-binding kinetochore proteins increase microtubule grip, as Ndc80 and Ska, complexes do, or whether the presence of some proteins instead reduce the grip to “lubricate” the attachment, remains an open question.

Here, we show that SKAP decreases the grip at the kinetochore-microtubule interface, effectively lubricating it. We use live imaging to show that SKAP increases the magnitude of metaphase kinetochore movements and the coordination between sisters and that it decreases the tension the sisters are under. Using laser ablation, we show that SKAP increases the velocity with which kinetochores move on both polymerizing and depolymerizing microtubules and that it makes the dynamics of attached microtubules more force responsive. Thus, not all kinetochore proteins increase the grip on microtubules: SKAP does exactly the opposite, reducing the friction at the interface. We propose that SKAP promotes accurate segregation by lubricating correct, mature attachments, ensuring that they can smoothly slide despite the mechanisms that stabilize them late in mitosis. More broadly, our work suggests that maintaining a strong yet dynamic kinetochore-microtubule interface not only requires components that grip—which are being actively studied—but also components that help slide, which are distinct from those that grip.

RESULTS

SKAP increases kinetochore mobility and is essential for sister kinetochore coordination in metaphase

To probe the mechanical role of the Astrin-SKAP complex at the kinetochore-microtubule interface, we live imaged metaphase chromosome movements in human retinal pigment epithelial-1 (human Rpe1), GFP-CenpA (kinetochore), and centrin1-GFP (centriole) cells (Rpe1-GFP, CenpA, and centrin1-GFP cells hereafter). Upon SKAP depletion by RNAi (siSKAP; Figures S1A and S1B), siSKAP kinetochore pairs oscillated less far from their mean position than the control (0.4 ± 0.2 μm versus 0.6 ± 0.2 μm SD; Figures 1B and 1C; Videos S1 and S2), as expected. siSKAP kinetochore pairs moved at a slower velocity than the control (1.2 ± 0.4 versus 1.8 ± 0.4 μm/min; Figures 1B and 1D; Videos S1 and S2), indicating that SKAP increases kinetochore mobility. This suggests that SKAP increases the kinetochore-microtubule interface dynamics. Additionally, the sister kinetochore movement coordination decreased without SKAP, with siSKAP sister kinetochore pairs showing a lower velocity correlation than the control sister pairs (0.54 ± 0.18 versus 0.74 ± 0.12; Figure 1E), with siSKAP sister kinetochores moving in opposite directions for a higher fraction of time than the control (29% ± 7% versus 17% ± 7%; Figure 1F). SKAP silencing using an alternative siRNA sequence confirmed the specificity of the oscillation phenotypes associated with SKAP silencing (Figures S1C–S1G). Furthermore, while in the control sister kinetochores, the front kinetochore usually reverses direction before the back kinetochore (Figures 1G and S1H), in siSKAP sisters, this preference was lost and the back kinetochore switched first more often than the control (41% versus 19%; Figure 1G). Together, these findings indicate that SKAP is essential for sister kinetochore mobility and coordination at metaphase.

SKAP decreases tension at the kinetochore-microtubule interface

The mechanical force from the sister kinetochore and from the spindle on chromosome arms is thought to coordinate sister kinetochore movement and inform directional kinetochore switching. To probe whether the miscoordination in the siSKAP sister kinetochore movement (Figures 1E–1G) could be due to defects in force generation or in how the kinetochore respond to force, we measured the interkinetochore (K-K) distance in siSKAP cells. Decreasing the activity of the microtubule-binding kinetochore proteins (such as Hec1 phosphorylation or Ska depletion) typically reduces the kinetochore’s grip or ability to sustain force before sliding on microtubules and thus leads to a lower K-K distance (Figure 2A). By contrast, we found that in live Rpe1-GFP cells, siSKAP kinetochore pairs had a higher K-K distance than the control (1.4 ± 0.2 μm versus 1.1 ± 0.1 μm; Figure 2B), consistent with some but not other previous reports. We used an alternative siRNA sequence to silence SKAP and confirmed that the increase in

K-K distance was a specific effect of SKAP silencing rather than an off-target effect of the siRNA used in this study (Figure S2A). In principle, an increase in K-K distance could stem from increased tension at the kinetochore-microtubule interface or decreased centromere stiffness. To test whether siSKAP cells could arrest at mitosis and thereby indirectly undergo cohesion fatigue and centromere softening, we imaged and measured mitotic duration (nuclear envelope breakdown [NEB] to anaphase onset) in Rpe1-GFP cells. The mitotic duration was ~24 min in the control and ~8 min longer in siSKAP cells (23.9 ± 5.8 versus 31.4 ± 15.0 min; Figure 2C). However, when we artificially induced mitotic arrest using the proteasome inhibitor MG132 (10 μM), the K-K distance only detectably increased starting from 106 min post MG132 (Figures S2B and S2C). Considering that just 6% of siSKAP cells had a mitotic duration longer than 100 min (Figure 2C), cohesion fatigue is unlikely responsible for increasing the K-K distance in siSKAP cells, as the mitotic delay observed in siSKAP cells is not long enough to induce this effect. To test whether SKAP could more directly affect centromere stiffness, we compared the chromosome movements in these MG132-treated cells with those in siSKAP cells (Figure S2). MG132-treated cells selected for their high mean K-K distance (Figure S2B), indicative of low centromere stiffness, had poor sister kinetochore velocity correlation, indistinguishable from siSKAP cells, but kinetochore velocity indistinguishable from the control (Figures S2D and S2E). Thus, although an effect on centromere stiffness cannot be fully excluded, SKAP cannot simply increase centromere stiffness. Consistent with SKAP not affecting centromere stiffness, treating Rpe1-GFP cells with nocodazole to remove microtubules and spindle forces led to reduced K-K distances that were indistinguishable between siSKAP and the control (0.7 ± 0.2 μm siSKAP versus 0.7 ± 0.1 μm control; Figures 2D and 2E). Thus, the increased K-K distance in siSKAP kinetochores depends on microtubules. Supporting this idea, laser ablating k-fibers in Rpe1-GFP cells to release spindle forces (Figures 2F and 2G) indicates that siSKAP kinetochores are under more tension than the control. As expected for a spring, sister pairs with higher K-K distances pre-ablation relaxed more post-ablation than those with lower K-K distances in both control and siSKAP cells (Figure 2H). Notably, K-K distance relaxed more post-ablation in siSKAP kinetochores than in the control (0.5 ± 0.2 μm versus 0.4 ± 0.1 μm; Figure 2I). This difference indicates that siSKAP kinetochores are under higher tension at the kinetochore-microtubule interface and is consistent with sister kinetochores coordinating movement more poorly (Figures 1E–1G). Thus, SKAP reduces tension at the kinetochore-microtubule interface, and not all microtubule couplers at the kinetochore increase tension at this interface.

**SKAP decreases kinetochore friction on polymerizing microtubules**

To decrease tension at the kinetochore-microtubule interface, SKAP could either reduce passive, frictional force; active, energy-consuming force generated at this interface; or both. At metaphase, the back sister kinetochore is typically bound to polymerizing microtubules through a largely passive interface and the front sister to depolymerizing microtubules through an interface that is both active and passive. Thus, decoupling the roles of SKAP at passive versus active interfaces requires uncoupling the effect of SKAP depletion at kinetochores in polymerizing and depolymerizing microtubules.

Since both sisters are attached together, exerting force on each other and holding on to microtubules in opposite polymerization states, we turned to laser ablation to decouple their responses. To probe kinetochores bound to polymerizing microtubules and generating passive force, we ablated k-fibers to trigger spindle-based force generation on a sister pair. k-fiber ablation generates new microtubule minus-ends that are recognized by dynein and pulled to the spindle pole (Figure 3A), which exerts an "external" force on the attached sister pair and induces microtubule polymerization at the back (away from the pole) kinetochore.

Assuming that this dynein pulling force is comparable between conditions, the velocity of this back kinetochrome reports on the passive, frictional force at its microtubule interface. We ablated k-fibers in Rpe1-GFP cells with and without SKAP (Figure 3B; Videos S3 and S4) and tracked both sisters. The velocity of the front kinetochrome was indistinguishable in siSKAP and control cells (3.2 ± 1.5 μm/min siSKAP versus 3.0 ± 1.4 μm/min in controls; Figures 3C and 3E). This is consistent with the dynein-generated force not being affected in siSKAP cells. By contrast, the back kinetochrome moved slower in siSKAP cells than in the control (2.0 ± 0.9 versus 2.8 ± 1.2 μm/min; Figures 3D and 3E). Although the front and back kinetochores moved at indistinguishable velocities in the control cells (3.0 ± 1.4 μm/min in front versus 2.8 ± 1.2 μm/min in back kinetochores), the back kinetochores moved at lower velocities than the front ones in siSKAP cells (2.0 ± 0.9 versus 3.2 ± 1.5 μm/min) (Figure 3E). This led to a...
persistent increase in the K-K distance during this sister kinetochore movement in siSKAP kinetochore pairs (Figure S3). Notably, the K-K distance at the time of back kinetochore directional switching (starting to move away from the pole) was higher in siSKAP kinetochores than in the control (1.4 ± 0.5 μm versus 1.0 ± 0.2 μm; Figure 3F), again suggesting that siSKAP kinetochores are less sensitive to force changes. Together, these findings indicate that SKAP decreases the friction between kinetochores and polymerizing microtubules.

Hec1 dephosphorylation is known to increase friction at the attachment interface.17,18 Hec1-S69 phosphorylation (by Aurora A) is maintained during mitosis and is required and sufficient to preserve kinetochore movement dynamics at metaphase.25 Therefore, we tested whether SKAP depletion affected the level of Hec1-S69 phosphorylation. Immunofluorescence quantification showed that SKAP depletion did not affect the kinetochore levels of Hec1-S69 phosphorylation (Figures 3G and 3H), indicating that the friction regulation by SKAP occurs independently of Hec1-S69 phosphorylation. Together, these findings indicate that SKAP, in contrast to the proposed role of other microtubule-binding proteins at the kinetochore,17,18,20,28 decreases the friction between kinetochores and polymerizing microtubules and does so through a mechanism independent of that setting Hec1’s basal dynamic state.28 SKAP could either do so by increasing the microtubule tip polymerization dynamics, producing an apparent change in friction, or by directly reducing the kinetochore friction on the microtubule lattice.

SKAP increases k-fiber depolymerization velocity and kinetochore force responsiveness

Given that SKAP regulates the kinetochore’s frictional interface with polymerizing microtubules (Figure 3), we asked whether it also regulates its interface with depolymerizing ones. To decouple both attached sister kinetochores and isolate SKAP’s role in depolymerizing microtubules, we laser ablated one kinetochore in a sister pair in Rpe1-GFP cells and tracked the movement of the remaining sister. As expected, the remaining sister was pulled poleward by depolymerizing microtubules and reversed direction near the pole, pushed by polar ejection forces3,9,12 (Figures 4A and 4B; Video S5). The poleward velocity of siSKAP kinetochores was slower than that in the control (2.1 ± 0.6 versus 3.5 ± 0.8 μm/min; Figures 4B–4D; Videos S5 and S6). This indicates that SKAP increases the velocity of microtubule depolymerization at the kinetochore interface. Here too, it could do so either by lowering the friction on the microtubule lattice or by increasing the depolymerization dynamics and thereby decreasing the apparent friction. Consistent with SKAP acting directly at the interface, SKAP depletion did not detectably change the kinetochore levels of key microtubule plus-end depolymerases involved in metaphase kinetochore movements, MCAK and Kif18A.47,48 (Figure S4). Further, in the same kinetochore ablation experiments, siSKAP kinetochores switched direction (to away from pole movement) closer to the pole than the control kinetochores as they got pushed by polar ejection forces (3.2 ± 1.2 versus 4.0 ± 1.8 μm; Figure 4E). Thus, SKAP increases the kinetochore’s force sensitivity when it is bound to depolymerizing microtubules, favoring a switch to the polymerization state, as observed after k-fiber ablation (Figure 3F) and during metaphase oscillations (Figure 1G). Together, these findings indicate that Astrin-SKAP does not increase the kinetochore’s grip on microtubules as other microtubule-binding proteins are thought to do but instead reduces grip, lowering friction and effectively lubricating the interface, making it more dynamic and force responsive.

DISCUSSION

Faithful chromosome segregation requires kinetochores to hold on to dynamic microtubules as they grow and shrink. Here, we ask the following: how does the mammalian kinetochore-microtubule interface stay dynamic and force responsive while maintaining a strong grip on microtubules? Mechanisms increasing the grip as attachments mature are being actively studied, including Ndc80 dephosphorylation17,18 and Ska recruitment19,20. Here, we combine molecular and mechanical perturbations to define the mechanical role of SKAP at this interface, and we show that it, in turn, decreases the grip at the interface. We demonstrate that SKAP increases sister kinetochore mobility and coordination in metaphase (Figure 1) and decreases the tension at the kinetochore-microtubule interface (Figure 2). We show that SKAP increases the velocity at which kinetochores move on both polymerizing (Figure 3) and depolymerizing (Figure 4) microtubules and that it makes the attachment more responsive to force changes (Figures 3 and 4). Together, our findings indicate that SKAP reduces the friction at the kinetochore-microtubule interface, effectively lubricating it. As such, and given SKAP’s arrival as kinetochores biorient,29,30 we propose that SKAP keeps the correct kinetochore-microtubule attachments dynamic to preserve them as they stabilize and mature.17,19 The association of SKAP mutations and changes in expression with some cancers and aneuploidy28,39,49 is consistent with SKAP’s lubrication function being key for faithful chromosome segregation.

Our work indicates that SKAP lowers the friction at the kinetochrome-microtubule interface, raising the question of what function a lower friction could serve. Basal levels of attachment dynamics are essential for accurate chromosome segregation.15,50 Ska recruitment and the gradual dephosphorylation of Hec1 increases the kinetochore’s grip on microtubules during mitosis.17–20 In contrast to other Hec1 phosphosites, S69 is persistently phosphorylated during mitosis, maintaining basal dynamics.28,39 Yet these dynamics are lost and friction increases upon SKAP depletion (Figures 1, 3, and 4), although the phosphorylation levels of Hec1-S69 are not affected by this depletion (Figures 3G and 3H). Thus, SKAP acts as a lubricant independently of Hec1-S69 phosphorylation. By reducing friction, SKAP may increase microtubule dynamics, increasing microtubule depolymerization (Figures 4B–4D) and poleward flux.35 To our knowledge, SKAP is the first microtubule binder proposed to decrease the friction at the kinetochore-microtubule interface. We propose that using SKAP to lower the friction, instead of loosening Ndc80-Ska’s grip to lower the friction, allows the cell to keep a dynamic kinetochore-microtubule interface without losing the grip of microtubules and attachment stability, by having one molecule specialized for each activity. Indeed, having distinct mechanisms to tune grip and dynamics may lead to finer regulatory control “knobs” to preserve stable attachments.
By lubricating the correct, bioriented attachments, SKAP could in principle help preserve them and prevent their increased microtubule affinity from making them less mobile and less responsive to force. The presence of more dynamic, lower friction interactions with microtubules could help stabilize attachments under force by increasing their adaptability to force changes. The force responsiveness of attachments is essential for accurate chromosome movement, alignment, and sister kinetochore coordination, and SKAP depleted cells have chromosome alignment and segregation defects. Indeed, we show that SKAP makes kinetochores more mobile and the kinetochore-microtubule interface more sensitive to force changes and that siSKAP attachments are under higher tension and inefficient at dissipating force and at responding to sister movement. This could explain why siSKAP attachments are under higher tension and inefficient at dissipating force and at responding to sister movement. It suggests that a function of lowering friction could be to make kinetochores responsive to...
force. While additional work will be needed to reveal how SKAP increases force responsiveness, in principle, lowering friction would be sufficient to do so.

Although SKAP reduces the friction at the kinetochore-microtubule interface (Figures 3A–3E), the mechanism by which it does so is not clear. SKAP depletion could in principle increase friction by reducing microtubule dynamics. However, lowering microtubule dynamics globally with drugs (such as taxol or eribulin) decreases interkinetochore tension (or K-K distance) rather than increasing it as we see for siSKAP (Figure 2).52,53 Thus, decreasing microtubule dynamics is not sufficient to recapitulate the effects of SKAP depletion. Further, we could not detect any change in the kinetochore recruitment of key microtubule dynamics regulators (MCAK and Kif18A) in siSKAP cells (Figure S4), and changing their activity is not consistent with our findings: MCAK depletion decreases both interkinetochore tension and microtubule depolymerization,57 and Kif18A depletion increases kinetochore velocity and oscillation amplitudes and decreases switching rates,48,51 and we do not see these observables change as such (Figures 1C, 1D, 2, 3F, and 4C–4E). Alternatively, SKAP might affect microtubule dynamics through its described interaction with the plus-end factor EB1.33,54 Contradicting this possibility, SKAP’s interaction with EB1 is not needed for SKAP’s role in chromosome alignment and spindle assembly, suggesting that SKAP’s role at the kinetochore-microtubule interface is independent of its interaction with EB1.55 Thus, although we cannot exclude the possibility that SKAP regulates the kinetochore activity of these or other microtubule dynamics regulators or directly affects microtubule dynamics, a change in microtubule dynamics alone is not sufficient to recapitulate all the behaviors of siSKAP cells. Together, these findings are consistent with SKAP playing a mechanical role at the kinetochore-microtubule interface and not simply regulating microtubule dynamics.

Mechanistically, SKAP could regulate the kinetochore-microtubule friction in different ways. One way in which it could do so is by changing the sliding friction of the other kinetochore proteins on microtubules. SKAP could induce conformational changes in Ndc80 or Ska complexes, which lower their friction on microtubules (model A; Figure 5), independently of Hec1-S69 phosphoregulation (Figures 3G and 3H). Alternatively, SKAP could directly bind microtubules and act as a kinetochore-microtubule coupler, as suggested by in vitro work.30,34,35 Accordingly, the microtubule-binding domain of SKAP is essential for its role in chromosome alignment and segregation.55 As such, SKAP could then compete out other microtubule binders that have a higher friction on microtubules (model B; Figure 5), as microtubule affinity (binding energy) and friction coefficient (transition state energy in moving between lattice binding sites) are not strictly coupled.56 The affinity of Ndc80-SKAP on microtubules35 is similar, although lower than that of Ndc80-Ska,16 suggesting that both complexes could compete for microtubule binding. If Ndc80-SKAP had a lower friction on microtubules than Ndc80-Ska, SKAP kinetochore localization could lower the friction at the kinetochore-microtubule interface. In principle, the above models hold independently of how SKAP is recruited to the kinetochore, for example, through local microtubule affinity regulation which is regulated by microtubule dynamics.58 The disassembly of such interfaces will require understanding not only how strong, robust interactions are achieved but also how the interface can remain dynamic. The latter may require looking beyond mechanisms that grip, as is the case for SKAP, which makes the human kinetochore-microtubule interface more dynamic.

**STAR METHODS**

Detailed methods are provided in the online version of this paper and include the following:

- **KEY RESOURCES TABLE**

---

**Current Biology 32, 1–11, June 20, 2022 9**

---
RESOURCES
- Lead contact
- Materials availability
- Data and code availability

EXPERIMENTAL MODEL AND SUBJECT DETAILS

METHOD DETAILS
- Cell culture, siRNA transfection and drug treatments in Rpe1 cells
- Immunofluorescence and immunoblotting
- Microscopy and laser ablation
- Study design and data inclusion criteria

QUANTIFICATION AND STATISTICAL ANALYSIS
- Analyzing fluorescence intensity
- Analyzing kinetochore behaviors
- Statistical analysis
- Video preparation

SUPPLEMENTAL INFORMATION

Supplemental information can be found online at https://doi.org/10.1016/j.cub.2022.04.061.

ACKNOWLEDGMENTS

We thank Iain Cheeseman for the anti-SKAP antibody and discussion, Jennifer DeLuca for the Hec1-pS69 antibody, Alexey Khodjakov for the Rpe1-GFP (GFP-Cenpa and centrin1-GFP) cells, and Charles Asbury and Rob Phillips for discussions. We thank the members of the Dumont Lab for their discussions and critical reading of the manuscript. This work was supported by NIH DP5GM119177, NIH R01GM134132, NIH R55GM136420, NSF CAREER 1554139, NSF 1548297, Center for Cellular Construction, the Rita Allen Foundation, and the Chan Zuckerberg Biohub (S.D.).

AUTHOR CONTRIBUTIONS

RESOURCE AVAILABILITY

**Lead contact**
Further information and requests for resources and reagents should be directed to and will be fulfilled by the lead contact, Sophie Dumont (sophie.dumont@ucsf.edu).

**Materials availability**
This study did not generate new unique reagents.

**Data and code availability**
All data reported in this paper has been deposited at Mendeley Data and is publicly available as of the date of publication (https://doi.org/10.17632/9gwpmj4hpr.1).
Rpe1-GFP cells (gift from A. Khodjakov, Wadsworth Center) were cultured in DMEM/F12 (Dulbecco’s Modified Eagle Medium; Nutrient Mixture F-12, Thermo Fisher Scientific, 11320082) supplemented with 10% qualified and heat-inactivated fetal bovine serum (FBS) (10438-026, Gibco) and penicillin/streptomycin and maintained at 37°C and 5% CO2. Cells used in this study were not authenticated by the authors.

**METHOD DETAILS**

**Cell culture, siRNA transfection and drug treatments in Rpe1 cells**

Cells were plated in 35 mm glass-bottom dishes (poly-D-lysine coated; MatTek Corporation) for live imaging experiments or in six wells plates after addition on #1. 1.25 mm coverslips (acid cleaned and poly-L-lysine coated) for immunofluorescence experiments. For knockdown experiments, siRNA targeting SKAP (siSKAP: 5’-AGGCUCACACUUCGAGUAA-3’

Received January 6, 2022; accepted April 26, 2022.

All original code has been deposited at github.com and is publicly available as of the date of publication (https://github.com/miquelrosassalvans/kinetochore-oscillations-analysis.git).

**Immunofluorescence and immunoblotting**

To validate the SKAP siRNA (Figures S1A and S1B), cells were seeded in six well plates, transfected with luciferase (control) or SKAP siRNA 24 h after transfection and processed for immunofluorescence experiments. Cells were collected in PBSX (Phosphate Buffered Saline solution) using a cell scraper and lysed in PBSX + 1% NP40 on ice for 30 min. Samples were run in a 4-12% Bis-Tris gel (Invitrogen, NPO335BOX) and transferred to a nitrocellulose membrane (Thermo Scientific, 88018). The following primary and secondary antibodies and dyes where used (incubated in TBS1X (Tris-buffered saline), 3% milk, 0.1% Tween for 1 h or 45 min, respectively): anti-SKAP (1ug/ml, rabbit, Origene, TA333584), anti-α-tubulin (DM1A, 1:1000, mouse, Sigma, T6199), goat anti-mouse IgG-HRP (1:1000, sc-2005, Santa Cruz Biotechnology) and mouse anti-rabbit IgG-HRP (1:1000, sc-2357, Santa Cruz Biotechnology). Blots were exposed with SuperSignal West Pico Substrate (Thermo Scientific) and imaged with a Bio-Rad ChemiDoc XRS+ system.

**Microscopy and laser ablation**

Samples were imaged using an inverted microscope or (Eclipse Ti-E; Nikon) with a spinning disk confocal (CSU-X1; Yokogawa Electric Corporation), head dichroic Semrock Di01-T450/488/568/647 for multicolor imaging, equipped with 405 nm (100 mW), 488 nm (120mW), 561 nm (150mW), and 642 nm (100mW) diode lasers, emission filters ET455/50M, ET525/50M, ET630/75M and ET690/50M for multicolor imaging, and an iXon3 camera (Andor Technology) operated by MetaMorph (7.7.8.0; Molecular Devices). Cells were imaged through a 100X 1.45 Ph3 oil objective and 1.5X lens.

For live imaging and laser ablation experiments, cells were maintained in a stage-top incubation chamber (Tokai Hit) at 37°C and 5% CO2. Metaphase oscillations were imaged every 3 s (Figures 1, 2B, and S2). Laser ablation (30-40 pulses of 3 ns at 20 Hz) with 514 nm light was performed using the MicroPoint Laser System (Andor). For laser ablation experiments, imaged were acquired more slowly prior to ablation and then acquired more rapidly after ablation (3 s prior and 0.5 s after k-fiber ablation, and 6 s prior and 3 s after kinetochore ablation [Figures 3 and 4, respectively]). Successful k-fiber ablation was verified by immediate K-K distance relaxation (Figures 2G–2I, 3, and S3) and posterior front kinetochore movement poleward by dynein pulling. Successful kinetochore ablation was verified by immediate poleward movement of the remaining sister kinetochore (Figure 4). For long term imaging experiments (Figure 2C), Rpe1-GFP cells treated with 100 nM SiR-DNA were imaged every 4 min for 18-20 h using a 20X objective.
Study design and data inclusion criteria
Two general criteria for inclusion of cells in metaphase oscillation and laser ablation experiments were applied. First, cells must express detectable levels of GFP-CenpA at kinetochores, but not so high as to completely label chromosome arms. Second, cells must be in metaphase, with a defined metaphase plate. For oscillation experiments (Figures 1, 2B, and S2), 2-4 kinetochore pairs per cell were analyzed, and the two kinetochores from the pair must stay in focus for a minimum of 90 s. For MG132 treatment experiments (Figure S2), cells with low centromere stiffness where selected if their mean K-K distance over time was higher than two standard deviations over the mean control K-K distance. For kinetochore speed calculations in ablation experiments (Figures 3E and 4D), kinetochore tracks shorter than 5 timepoints were excluded due to the absence of a consistent directional movement.

We did not pre-estimate a required sample size before performing experiments nor did we blind or randomize samples during experimentation or analysis. The ablation experiments in this study are low throughput by nature, which does not enable us to report averages from multiple independent replicate experiments. Instead, we pool cells from across different independent experiments (with at least three independent experiments per condition per assay).

QUANTIFICATION AND STATISTICAL ANALYSIS

Analyzing fluorescence intensity
Images from immunofluorescence experiments were processed and fluorescence intensity was quantified using FIJI (Version 2.3.0/1.53f). For protein intensity measurements, a color threshold mask (Yen method) was applied using the CREST or Hec1 signal (for kinetochore selection) or DM1A signal (for spindle microtubule selection) to define the areas in which the fluorescence intensity would be measured for each protein of interest. Fluorescence intensity was measured for the proteins of interest (Hec1-S69, MCAK, Kif18A) and for the reference (CREST, Hec1 or Tubulin). Intensity of the protein of interest was normalized by the kinetochore or microtubule marker intensity by dividing the total intensity of the protein of interest by the intensity of the reference in the selected area. Figures 3H, S4C, and S4D showing data from individual representative experiments, three independent experiments were performed for each quantification, obtaining comparable results.

Analyzing kinetochore behaviors
Kinetochores and centrioles were manually tracked from GFP-CenpA/cenrin1-GFP videos using the MtrackJ plugin from FIJI. GFP-centriole position was used as a marker for the spindle pole position. Kinetochore position was calculated as the distance from the spindle pole position. In metaphase oscillations experiments, all quantifications and statistical analyses were performed using home-written Phyton code (https://github.com/miquelrosassalvans/kinetochore-oscillations-analysis.git). Kinetochore speed at each timepoint was calculated as the difference in kinetochore position between two consecutive timepoints. Kinetochore speed was calculated by obtaining the slope of the best fitting regression line of individual kinetochore tracks (Figures 3E and 4D) or of entire tracks together (Figures 3C, 3D, and 4C). Sister kinetochore movement coordination was obtained by calculating the correlation of sister kinetochore velocity over time or by the percentage of timepoints in which sister kinetochore movement direction was opposite. Kinetochore directional switch was determined by the consistent movement of a kinetochore in a new direction for 3 consecutive timepoints. In ablation experiments, time after ablation was measured from the fist timepoint immediately after ablation. In all experiments, a kinetochore directional switch was defined by the consistent movement of the kinetochore in the opposite direction for a period of 3 consecutive timepoints (9 s in oscillations and kinetochore ablations and 1.5 s for k-fiber ablation experiments). K-K distance was calculated by subtracting the position of sister kinetochore A from sister kinetochore B, obtaining the length of the vector, and calculating the K-K distance average over time for each kinetochore pair. K-K distance relaxation was obtained by subtracting the K-K distance at the first timepoint after ablation from the last timepoint before ablation.

Statistical analysis
Statistical analysis was performed in Phyton or Graphpad (Prism 9). The Fisher’s exact test was used in Figure 1G, Student’s t test was used for parametric datasets (Figures 2B, 2I, 3E, 3H, 4E, S4C, and S4D), Mann-Whitney test for non-parametric datasets (Figures 1C–1F, 2C, 2E, 3F, 4D, S2A, S2C, and S2D) and analysis of covariance test, ANCOVA, for linear regression slopes comparison (Figures 3C, 3D, 4C, and S3).

Video preparation
Videos were prepared using FIJI. Brightness and contrast were linearly adjusted to clearly visualize the kinetochores and centrioles.
