INTRODUCTION

Although several novel diagnostic tests for tuberculosis infection have been developed and commercially licensed in recent years, the tuberculin skin test (TST) is still widely used for identifying latent tuberculosis infection (LTBI). Several difficulties exist, however, in the application and interpretation of the TST. For example, the reaction may be accentuated on repeated test, which can cause the test to be misinterpreted as a skin test conversion (1). The prevalence of boosted reaction is generally correlated with the prevalence of initial tuberculin reactions and is particularly common in individuals who have been vaccinated with bacille Calmette-Guérin (BCG) (1-4). Therefore, an evaluation of the prevalence of boosted reaction and the associated factors would be important for the assessment of TST reactivity in countries that have a high prevalence of tuberculosis (TB) and a routine BCG vaccination policy.

The objectives of this study were to estimate the rate of boosted reaction and to evaluate the associated factors among military personnel in a setting with an intermediate burden of TB and routine BCG vaccination policy.

MATERIALS AND METHODS

Some South Korean troops, mostly engineers, have been operating in Afghanistan on a 6-month rotation since 2002 to help with the reconstruction effort in that war-torn country. As part of the TB control program of the Armed Forces Medical Command, Republic of Korea, the troops dispatched to Afghanistan, which have shown a high incidence of TB (168 cases per 100,000 population per year) (8), have undergone screening tests for TB in addition to a medical examination before and after deployment at the Armed Forces Capital Hospital since 2006.

We performed two-step TSTs on the troops that were to be dispatched to Afghanistan for 6-month missions as described above in August 2006 with the approval of the ethics committee of the Armed Forces Medical Command and after obtaining informed consent from each subject. Before the skin tests were performed, the troops completed questionnaires.

This study was performed to estimate the rate of boosted reaction in the two-step tuberculin skin test (TST) and to evaluate the associated factors among military personnel of South Korea, which has an intermediate burden of tuberculosis (TB) and a routine bacille Calmette-Guérin (BCG) vaccination policy. Two-step TST was performed on 264 military personnel who did not have a history of close contact to TB. Subjects with a negative reaction to the first test of <10 mm had a second TST applied 1 week later on the other forearm. A positive result (≥10 mm) on the initial TST was observed in 126 (48%) of the subjects. A boosted reaction on the second TST developed in 32 (23%) of the 124 subjects with a negative initial TST. In multiple logistic regression analysis, the size of the initial TST reaction was the only factor associated with a boosted reaction on the second TST. The high rate of boosted reaction among healthy adults in South Korea suggests that two-step TST should be performed to assess the baseline TST reactivity in settings with an intermediate burden of TB and routine BCG vaccination policy, especially among subjects with an initial TST reaction that is ≥5 mm.

Key Words: Tuberculin Test; Hypersensitivity; Mycobacterium bovis; Korea
naires about previous TSTs, potential exposure to TB, treatment for TB, and other demographic data. Subjects were excluded from this study if they had a documented history of TB or a history of close contact to TB. Because the records of previous BCG vaccination were not available for most subjects, the presence of a typical BCG scar was accepted to indicate previous BCG vaccination (9).

**Tuberculin testing**

TSTs were administered by injecting 0.1 mL of 2 tuberculin units of purified protein derivative (RT 23; Statens Serum Institute, Copenhagen, Denmark) into the anterior surface of the forearm with disposable syringes and 27-gauge needles using the intradermal Mantoux method. Reactions were read 48-72 hr after the injection by a trained nurse, and the largest transverse diameter of palpable induration was recorded in millimeters. At the time of reading, the nurse was unaware of each subject’s BCG vaccination status. A positive TST result was defined as an induration of 10 mm or more in diameter. Subjects with a reaction of <10 mm to the first test had a second TST applied 1 week later on the other forearm. The techniques for testing and reading were the same as for the initial TST. A boosted reaction was defined as a reaction of ≥10 mm on the second TST with a ≥6 mm increase than on the first TST result (4).

**Statistical analysis**

Data were analyzed using SPSS 12.0 (SPSS Inc, Chicago, IL, U.S.A.). To evaluate possible association between boosting reaction and variables, odds ratio with 95% confidence intervals (95% CI) were calculated. The likelihood ratio test was used to assess the significance of this association. Then, multiple logistic regression analysis was used to determine the independent factors associated with boosting reaction.

**RESULTS**

In total, 264 troops were recruited to have a medical examination during the study period. Of these troops, 126 (48%) had a positive result on the initial TST and were excluded from further testing. Of the remaining 138 subjects with a negative initial TST (≤9 mm), 14 subjects refused the second TST and were excluded. The characteristics of the remaining 124 (47%) subjects are presented in Table 1. The subjects ranged in age from 20 to 47 yr, with a median age of 22 yr, and all of the subjects were male. None of the subjects had a previous history of TST. Abnormal findings were not observed on chest radiography or in the other laboratory tests performed for the medical examination. A BCG scar was present in 112 subjects (90%), and boosted reaction was observed in 32 (23%) subjects. As shown in Table 2, boost-

### Table 1. Characteristics of the study subjects who received a two-step tuberculin skin test (TST)

| Characteristics          | No. of subjects (%) |
|--------------------------|---------------------|
| Age group                |                     |
| 20-29 yr                 | 110 (88.7)          |

### Table 3. Factors associated with the boosting reaction on second tuberculin skin test (TST) by multiple logistic regression analysis

| Associated factors | Adjusted OR (95% CI) |
|--------------------|----------------------|
| Age (yr)           |                      |
| 20-29              | 1.00                 |
| 30-39              | 1.29 (0.33-5.12)     |
| 40-49              | 1.46 (0.09-24.80)    |
| BCG scar           |                      |
| Absent             | 1.00                 |
| Present            | 2.10 (0.41-10.74)    |
| Initial TST reaction |                      |
| 0                  | 1.00                 |
| 1-4                | 3.48 (0.85-14.16)    |
| 5-9                | 6.25 (1.93-20.29)    |

OR, odds ratio; CI, confidence interval; BCG, bacille Calmette-Guerin.
ed reaction was not associated with increasing age or the presence of a BCG scar ($p=0.618$ and $0.427$, respectively). The size of the initial TST reaction was significantly associated with boosted reaction ($p=0.004$). In multiple logistic regression analysis, the size of the initial TST reaction was the only factor associated with boosted reaction on the second TST (Table 3).

### DISCUSSION

In the present study of the TST reactivity in Korean military personnel, boosted reaction on the second TST developed in 23% of the subjects with a negative reaction on the initial TST and was associated with the size of the initial TST reaction.

The definitions of a boosted reaction have differed in previous studies, and the rates of boosted reactions for two-step TSTs have ranged from 0 to 59% (5-7, 10-19). The variation in the rates of boosted reactions among different studies reflects differences in the populations studied regarding age, BCG vaccination status, and previous exposure to TB or nontuberculous mycobacteria. Therefore, we found that the prevalence of a negative reaction on the second TST was high among adults in a setting with an intermediate incidence of TB and routine BCG vaccination program as in South Korea; that study found high positive rates of boosted reactions (21%) (6). Even though the majority of our subjects were younger than 30 yr (89%), our rate of boosted reactions was 11-17% higher than the rates reported by two other studies performed in countries with a high prevalence of TB and routine BCG vaccination (5, 7). This difference might be attributable to the different proportions of males, who are reportedly more likely to be positive of boosted reaction (11, 20).

Previous BCG vaccination has been reported to be one of the most influential factors for boosted reaction (10, 12, 13, 16, 19, 20). In the present study, however, the presence of a BCG scar was not associated with an increased rate of boosted reaction. The lack of a BCG effect in our subjects could have occurred because most BCG vaccinations in Korea are performed during infancy; the prevalence of a BCG scar in infants was approximately 88% during the seventh nationwide TB prevalence survey in Korea (21). Menzies et al. (12) reported that BCG vaccination received in infancy has little effect on the boosted reaction. In addition, previous studies have documented a relationship between increasing age and boosted reaction (5, 11-13); therefore, it is likely that we did not observe a statistically significant relationship because of the small number of older subjects in our study population.

The prevalence of an initial TST reaction has been correlated with the prevalence of the boosted reaction (12, 22, 23). We found that the rate of positive boosted reaction as the size of the initial TST reaction increased. Menzies et al. (12) reported a frequency of boosted reactions of 3.7, 17.1, and 28.4% in subjects whose initial TST reactions measured 0, 1-4, and 5-9 mm, respectively. Alvarez et al. (22) found that the rate of boosted reactions was 12.7 and 35.5% in subjects with an initial reaction measuring 0-4 and 5-9 mm, respectively. In the present study, the rates of boosted reactions were 10, 25, and 38% in subjects with an initial TST reaction measuring 0, 1-4, and 5-9 mm, respectively ($p=0.004$), and the size of the initial TST reaction was the only factor associated with boosted reaction on the second TST in multiple logistic regression analysis.

Health care workers are at high risk for TB, and screening of health care workers for TB is an important component of infection control programs (1). However, little is known about the TST reactivity in an adult South Korean population. This is the first study to report the boosted reaction in an adult South Korean population. Therefore, our results suggest that the boosted reaction on repeated test should be considered when TB screening of health care workers, who are likely to receive periodic retesting, would be performed hereafter in South Korea.

In conclusion, the prevalence of boosted reaction on repeated TST was high among adults in a setting with an intermediate burden of TB and routine BCG vaccination policy, and the size of the initial TST reaction was the only associated factor on multiple logistic regression analysis. Therefore, to avoid misinterpreting the boosted reaction on subsequent TST as a conversion, the use of a two-step TST would be necessary to assess the baseline TST reactivity among subjects with a negative reaction on initial TST, especially when the size of the initial TST is >5 mm.
