(Dated: May 8, 2018)

We present a novel quasiparticle state driven by a supercurrent in GaAs (100) quantum wells in proximity to an s-wave superconductor, which can be tuned by the superconducting velocity. Rich features such as the suppressed Cooper pairings, large quasiparticle density and non-monotonically tunable momentum current can be realized by varying the superconducting velocity. In the degenerate regime, the quasiparticle Fermi surface is composed of two arcs, referred to as Fermi arcs, which are contributed by the electron- and hole-like branches. The D’yakonov-Perel’ spin relaxation is explored, and intriguing physics is revealed when the Fermi arc emerges. Specifically, when the order parameter tends to zero, it is found that the branch-mixing scattering is forbidden in the quasi-electron band. When the condensation process associated with the annihilation of the quasi-electron and quasi-hole is slow, this indicates that the electron- and hole-like Fermi arcs in the quasi-electron band are independent. The open structure of the Fermi arc leads to the nonzero angular-average of the effective magnetic field due to the spin-orbit coupling, which acts as an effective Zeeman field. This Zeeman field leads to the spin oscillations even in the strong scattering regime. Moreover, in the strong scattering regime, we show that the open structure of the Fermi arc are also leads to the insensitiveness of the spin relaxation to the momentum scattering, in contrast to the conventional motional narrowing situation. Nevertheless, with a finite order parameter, the branch-mixing scattering can be triggered, opening the inter-branch spin relaxation channel, which is dominant in the strong scattering regime. In contrast to the situation with an extremely small order parameter, due to the inter-branch channel, the spin oscillations vanish and the spin relaxation exhibits motional narrowing feature in the strong scattering regime.

I. INTRODUCTION

In recent years, the superconducting spintronics has attracted much attention for providing new methods to control over the spin degree of freedom based on the spin-triplet Cooper pairs and Bogoliubov quasiparticles. On one hand, the triplet Cooper pairs combine both the features of the spintronics and superconductivity, offering the possibility to realize the spin-polarized supercurrent. On the other hand, as the quasi-particle charge depends on its momentum in the conventional superconductor, which is exactly zero at the Fermi momentum, it is promising to tune the spin degree of freedom with weak disturbance on the charge one in one system. To reveal the physics in the superconducting spintronics, the spin dynamics for both the spin-polarized Cooper pairs and quasiparticles has been intensively studied.

Specifically, for the quasiparticle, rich physics has been reported in the studies on the charge or spin injection from the non-magnetic metal or ferromagnet to the conventional superconductor. It is shown that the injection of one electron with charge e into the superconductor can add one Cooper pair with charge 2e and spin 0 and a quasiparticle with charge e and spin 1/2, respectively. Here, \( \tilde{v}_k = 1/2 + \tilde{z}_k/(2E_k) \) and \( \tilde{v}_k = 1/2 - \tilde{z}_k/(2E_k) \), in which \( \tilde{z}_k = \varepsilon_k - \mu_S \) with \( \varepsilon_k \) representing the kinetic energy of the electron and \( \mu_S \) being the chemical potential in the superconductor; \( E_k = \sqrt{v_k^2 + |\Delta_S|^2} \) denotes the energy spectrum of the quasiparticle with \( \Delta_S \) being the superconducting order parameter. Accordingly, in the steady state, the injected charge and spin are mainly carried by the Cooper pairs and quasiparticles separately, indicating that the spin-charge separation can be realized during the injection. It is further noticed that in the process of the charge and spin injections, the non-equilibrium charge and/or spin imbalance can be created. It is then revealed that in the dynamical process, to maintain the charge neutrality, the Cooper pair condensate can respond to the dynamics of the injected quasiparticles. Accordingly, the study on the quasiparticle dynamics itself is essential to further reveal the dynamics of Cooper pairs.

Among the quasiparticle dynamics, the spin dynamics in the superconducting metals has been studied both theoretically and experimentally. Theoretically, the quasiparticle spin relaxation has been calculated by considering the spin-flip and spin-orbit scatterings due to the impurities which lies in the Elliott-Yafet mechanism. In the superconducting state, it is shown that the spin-flip scattering is efficiently enhanced due to the enhancement of the density of states.
(DOS)\textsuperscript{18,21,25}. Whereas the spin-orbit scattering is efficiently suppressed due to the coherence factor $\zeta_k/E_k$ in the scattering term\textsuperscript{15}. Experimentally, the long injection lengths were reported for the spin injected into the superconducting Al\textsuperscript{26,27} and Nb\textsuperscript{31} indicating the long spin relaxation time (SRT) in the superconducting state compared to the normal one. Furthermore, it is further found that the injected spin current in the superconducting Al can significantly influences the quasiparticle SRT, with the spin relaxation behavior in the superconducting state resembling the normal one when the injected spin current is large.\textsuperscript{44} As rich physics is revealed in the Elliott-Yafet mechanism in the superconducting metal, it is intriguing to study the D’yakonov-Perel’ (DP) mechanism,\textsuperscript{38} which is more important for materials without center-inversion symmetry, in the superconducting state. Furthermore, the proximity-induced superconductivity has been realized in InAs\textsuperscript{39,40} and GaAs\textsuperscript{41–44} heterostructures, offering the chance to study the DP mechanism in the superconducting semiconductors.

It is noted that in the study of the dynamics in superconducting system, different kinetic equations based on the quasiclassical\textsuperscript{13,15,44–59} and quasiparticle\textsuperscript{48,21,60,69} approximations are used. The quasiclassical approximation is applicable for the system with a large Fermi energy, in which the dependence on the momentum magnitude is neglected in the Green function, whereas the frequency and angle-of-momentum dependencies are explicitly considered. For the quasiparticle approximation, in the Green function, the dependencies on the angle and magnitude of the momentum are explicitly considered, but the frequency dependence is not emphasized. Moreover, this approximation is applicable only when the perturbation on the superconducting order parameter is not strong, and hence the quasiparticle energy spectrum is well defined.\textsuperscript{54,61,64} To the best of our knowledge, the quasiparticle approximation is mainly applied to the system without the SOC.\textsuperscript{18,21,60,67} When there exists the SOC, Einzel \textit{et al.} derived the kinetic equation based on the quasiparticle approximation, nevertheless in which the scattering is not considered.\textsuperscript{68,69} The kinetic equations of quasiparticle with the scattering term explicitly considered in the presence of the SOC are still absent, even for the simplest case with the $s$-wave order parameter.

In this work, we investigate the DP spin relaxation with superconducting-velocity–tunable quasiparticle state in GaAs (100) quantum wells (QWs) in proximity to an $s$-wave superconductor. A novel quasiparticle state is predicted in the superconducting QWs, based on which the quasiparticle spin relaxation is then explored. In the $s$-wave superconductor, the order parameter, i.e., $\Delta_S = |\Delta_S|e^{i\Lambda}$, is contributed by its magnitude $|\Delta_S|$ and superconducting phase $\Lambda$. Then due to the superconducting proximity effect,\textsuperscript{16,20,73} by assuming that the superconducting phase is not disrupted by the disorder, an $s$-wave order parameter with the same superconducting phase at the superconductor-semiconductor interface but different magnitude $|\Delta|$ can arise in the semiconductor. Specifically, with the inhomogeneous superconducting phase, a superconducting velocity $v_s = \nabla\Delta/m^* \equiv q/m^*$ arises with $m^*$ being the electron effective mass in the QWs.\textsuperscript{74,75} Here, it is assumed that $v_s$ is perpendicular to the growth direction of QWs, from which a supercurrent is induced. In this work, it is further assumed that the superconducting velocity is small, which marginally influences the superconducting state in the $s$-wave superconductor.\textsuperscript{74,75} However, when $|\Delta| \ll |\Delta_S|$, the superconducting velocity can efficiently tune the superconducting state in QWs.

We show that in the superconducting QWs, the superconducting velocity can cause the tilt of the quasiparticle energy spectrum. Specifically, in the presence of the supercurrent, the energy spectra of the quasi-electron ($+$) and quasi-hole ($-$) are

$$E_{k}^{\pm} = k \cdot v_s/2 \pm \epsilon_k. \quad (1)$$

Here, $\epsilon_k = \sqrt{\epsilon_k^2 + |\Delta|^2}$ with $\epsilon_k = k^2/2m^* + v_s^2/2 - \mu$ with $\mu$ being the chemical potential in the semiconductor ($h \equiv 1$ throughout this paper). It is noted that the chemical potential is shifted by $-m^*v_s^2/8$ due to the superconducting velocity. From Eq. $1$, for the quasi-electron band, when $|\Delta| \rightarrow 0$, $E_{k}^{+} \approx (k + q/2)^2/(2m^*) - \mu$ if $|k| > k_F$ and $E_{k}^{+} \approx -(k - q/2)^2/(2m^*) + \mu$ if $|k| < k_F$. With the former and latter branches referred to as the electron- ($\zeta_k > 0$ with negative charge) and hole-like ($\zeta_k < 0$ with positive charge) branches, it can be seen that the superconducting velocity leads to the shifts of the electron- and hole-like branches by $q/2$ and $-q/2$, respectively. Then the tilt of the quasiparticle energy spectrum can be simply understood.

In Fig. $1(a)$ [$1(b)$], the quasi-electron (quasi-hole) energy spectrum is schematically plotted with $|\Delta| \rightarrow 0$ when $v_s \equiv q/m^* = 0$ ($v_s \neq 0$) by the red solid (green dashed) curves. It can be seen that the quasi-electron (quasi-hole) band is composed by the positive (negative) parts of the electron and hole bands, shown by the curves labeled by the dots and stars. Due to the superconducting velocity, compared to Fig. $1(a)$, the electron and hole-bands are shifted by $q/2$ and $-q/2$, respectively, and hence the resulting quasiparticle energy spectrum is tilted [Fig. $1(b)$]. Specifically, the tilted excitation energy can be even smaller than the chemical potential $\mu$, represented by the blue chain line in Fig. $1$. Accordingly, the quasi-electrons mainly populate at the region with the negative excitation energy even at zero temperature, which is referred to as the blocking region.\textsuperscript{26,78}

In Fig. $1(b)$, the blocking region for the quasi-electron is schematically represented by the green “crescent”, whose formation can be treated as the shift of the Fermi surfaces of the electron and hole. The appearance of the blocking region can significantly influence the Cooper pairings, quasiparticle density and momentum current driven by the supercurrent in QWs.\textsuperscript{74,78}

Specifically, we show that driven by the supercurrent, the center-of-mass momentum $q$ is carried by the
FIG. 1: (Color online) Schematic showing the tilt of the quasiparticle energy spectrum and formation of the blocking region. Here, $|\Delta|$ is taken to be extremely small. In (a) [(b)], $\nu_s \equiv q/m^* = 0$ ($\nu_s \neq 0$). The red solid (green dashed) curves represent the quasi-electron (quasi-hole) energy spectrum; whereas the curve labeled by the dots (stars) denotes the electron (hole) band. (b), compared to (a), due to the superconducting velocity, the electron and hole-bands are shifted by $q/2$ and $-q/2$, respectively, and hence the resulting quasi-electron energy spectrum is tilted. When the quasi-electron energy is tilted to be smaller than the chemical potential $\mu$ represented by the blue chain line, the blocking region emerges, which is represented by the green region in the crescent shape in (b). Finally, it is addressed that with $|\Delta|$ tending to zero, the branch-mixing scattering due to the impurity (represented by the black arrow) is forbidden without and with the supercurrent.

Cooper pairs, with the anomalous correlations only existing between the states with momentum $k + q/2$ and $-k + q/2$. Moreover, we show that the anomalous correlations around the Fermi surface are efficiently suppressed due to the emergence of the blocking region (refer to Sec. III B 1). Furthermore, the quasiparticle density increases with the increase of the superconducting velocity. In this process, the system experiences the crossover between the non-degenerate and degenerate limits. Finally, it is revealed that when the blocking region appears, the momentum current contributed by the quasiparticles flows in the opposite direction to the one due to the Cooper pairs. Accordingly, due to the competition of the Cooper pairs and quasiparticles in the blocking region, there exists a peak in the superconducting-velocity dependence of the momentum current, whose position corresponds to the appearance of the blocking region.

We then study the quasiparticle spin relaxation in the superconducting QWs. Based on the quasiparticle approximation due to the small Fermi energy in QWs, the kinetic spin Bloch equations (KSEs) for quasiparticle is set up with the SOC and quasiparticle-impurity scattering explicitly considered. By using the KSEs, we calculate the SRT without and with the superconducting velocity, respectively. Rich physics is revealed. Without the supercurrent, we address that the branch-mixing scattering is referred to as the scattering of quasiparticles between the electron-like and hole-like branches. This indicates that the electron- and hole-like branches are independent and hence only the intra-branch spin relaxation channel exists. In this situation, when $|\Delta|$ tends to zero, the SRT recovers to the normal one. Whereas with a finite order parameter, it is found that in the superconducting state, no matter the scattering is weak or strong, the SRT is enhanced compared to the normal one, whereas the boundary between the weak and strong scattering regimes is unchanged. This comes from the efficient suppressions of the SOC and impurity scattering for the quasiparticle by the same factor $|c_k|/\epsilon_k$.

With the supercurrent, the quasiparticle spin relaxations with extremely small ($|\Delta| \ll 0.1$ meV) and finite ($|\Delta| \gtrsim 0.1$ meV) order parameters are explored. When the order parameter is extremely small (e.g., $|\Delta| = 0.01$ meV), the branch-mixing scattering is still forbidden [refer to Fig. 1(b)]. This is because the coherence factor $( \approx c_k/|c_k| + \epsilon_k/|\epsilon_k|)$ in the quasiparticle-impurity scattering tends to zero. However, differing from the situation without the supercurrent, when the blocking region emerges, the Fermi surfaces from the electron- and hole-like branches are not closed, referred to as “Fermi arcs”.

In Fig. 2, the Fermi arcs from the electron- and hole-like branches are represented by the gray and red dashed curves in the left and right boundaries of the blocking region. One observes that in the electron- or hole-like Fermi arc, the angular-average of effective magnetic field due to the SOC (i.e., $\Omega_k$) is not zero. When the condensation process is slow, which can be associated with the annihilation of quasi-electron and quasi-hole, the spin polarizations mainly relaxes within the Fermi arcs.

It is revealed that the quasiparticle spin relaxation at the Fermi arc exhibits anomalous features in the strong scattering regime. Specifically, on one hand, the spin oscillations can be induced by the superconducting velocity; on the other hand, the spin relaxation becomes insensitive to the momentum scattering. The latter phenomenon is in contrast to the conventional DP relaxation, where the spin relaxation is suppressed by the momentum scattering (motional narrowing effect). We reveal that the nonzero angular-average of the SOC in one Fermi arc corresponds to an effective Zeeman field. This effective Zeeman field can cause the spin oscillations even in the strong scattering regime, which nevertheless has little influence on the spin relaxation. Actually, this feature provides a direct proof for the existence of the Fermi arc. It is further shown that by switching off the effective Zeeman field, the magnitude of the residue effective magnetic field strongly depends on the direction of the momentum, causing an effective modular-dependent inhomogeneous broadening even for the elastic scattering.

This modular-dependent inhomogeneous broadening can be enhanced by the momentum scattering in the strong scattering regime and tends to enhance the spin relax-
ation. Nevertheless, the motional narrowing effect tends to suppress the spin relaxation.\textsuperscript{22} Thus, the competition of the two opposite trends leads to the insensitivity of momentum scattering dependence of the SRT in the strong scattering regime.

![Diagram of intra- and inter-branch spin relaxation processes. The blocking region is represented by the green area in the crescent shape. Around the blocking region, its left (right) boundary represented by the gray (red) dashed curve mainly comes from the electron(hole)-like Fermi arc, which is referred to as the electron(hole)-like Fermi arc in this work. Around the electron- and hole-like Fermi arcs, the red solid and blue dashed arrows denote the effective magnetic field due to the SOC (i.e., $\Omega_k$). With extremely small order parameter, the branch-mixing scattering is forbidden, and the spin polarization in the electron- and hole-like bands relaxes independently. This is referred to as the intra-branch spin relaxation. Whereas with the finite order parameter, the quasiparticles can be efficiently scattered between the left and right boundaries of the blocking region (e.g., scattering from $A$ to $A'$), triggering the branch-mixing scattering.\textsuperscript{21,25} This opens the inter-branch spin relaxation channel.

When the order parameter is big enough (i.e., $|\Delta| \gtrsim 0.1$ meV in our model), in the presence of the supercurrent, it is revealed that the tilt of the energy spectrum can trigger the branch-mixing scattering. In this situation, there exist the intra- and inter-branch spin relaxation channels for the quasiparticle spin relaxation, as illustrated in Fig. 2. Furthermore, we reveal the role of the intra- and inter-branch spin relaxation channels on the spin relaxation in both the weak and strong scattering regimes. Specifically, in the weak scattering regime, the intra-branch spin relaxation channel is dominant; whereas in the strong scattering regime, the interbranch channel becomes dominant when the blocking region appears. Moreover, in the strong scattering regime, with the branch-mixing scattering efficiently triggered, the quasi-electron can feel all the SOC around the Fermi surface, whose angular-average is zero (refer to Fig. 2). Accordingly, in the strong scattering regime, in contrast to the situation with extremely small order parameter, no spin oscillation occurs. Furthermore, in this situation, the inhomogeneous broadening becomes the conventional one and hence the spin relaxation is suppressed by the momentum scattering, exhibiting the motional narrowing feature.

This paper is organized as follows. We first lay out the Hamiltonian in Sec. II. In Sec. III, we analyze the quasiparticle state in the superconducting QWs both analytically (Sec. III A) and numerically (Sec. III B). In Sec. IV, the quasiparticle spin relaxation is studied by using the KSBE, derived in the quasiparticle approximation. We conclude and discuss in Sec. V.

II. HAMILTONIAN

In this section, we present the Hamiltonian of the symmetric (100) QWs in proximity to an $s$-wave superconductor. In the particle space, the Hamiltonian is composed by the Bogoliubov-de Gennes (BdG) Hamiltonian and electron-impurity interaction. The BdG Hamiltonian is written as\textsuperscript{16,70-73}

$$H_0 = \int \frac{d^2r}{2} \Phi^\dagger(r) \begin{pmatrix} \zeta_k & h_k & 0 & \Delta(r) \\ h^*_k & -\Delta^*(r) & -\zeta_k & 0 \\ 0 & -\Delta^*(r) & h^*_k & \zeta_k \\ \Delta(r) & 0 & h_k & -\zeta_k \end{pmatrix} \Phi(r),$$

(2)

where $\Phi(r)$ is the particle field operator. Here, $\zeta_k = k^2/(2m^*) - \mu$; $h_k = -\alpha k_x - i\gamma k_y$ comes from the Dresselhaus SOC\textsuperscript{82} in which $\alpha = \gamma_D (\pi/a)^2$ for the infinitely deep well with $\gamma_D$ and $a$ being the Dresselhaus coefficient and well width, respectively; $\Delta(r) = |\Delta| e^{i\mathbf{q} \cdot \mathbf{r}}$ is the $s$-wave order parameter. Specifically, $|\Delta|$ and $\mathbf{q}$ are assumed to be homogeneous in this work.

The electron-impurity interaction is expressed as

$$H_{\text{im}} = \frac{1}{2} \int d^2r \Phi^\dagger(r)V(r)\tau_3\Phi(r),$$

(3)

with $\tau_3 \equiv \text{diag}(1,1,-1,-1)$ and $V(r)$ denoting the screened Coulomb potential, whose Fourier component $V_k = V^0_k/(1 - P^{(1)} V^0_k)$. Here, $V^0_k = \int dy \frac{1}{\pi a |I(y)|^2} e^{2\pi i y^2/(2y^2 + 2y^2/a^2)}$, with $\varepsilon_0$ and $\kappa_0$ representing the vacuum permittivity and relative dielectric constant; $|I(y)|^2 = \frac{\pi^{1/2} \sin^2(y)}{(\pi y^2 + y^2)^{3/2}}$ standing for the form factor; $P^{(1)}$ denoting the longitudinal polarization function, whose expression has been derived in Ref. 16.

In the momentum space, the BdG Hamiltonian is further represented as

$$H_0(k) = \frac{1}{2} \sum_k \Phi^\dagger_k \begin{pmatrix} \zeta_k + \frac{2}{3} & h^*_k + \frac{2}{3} & 0 & |\Delta| \\ h^*_k + \frac{2}{3} & -\zeta_k + \frac{2}{3} & -|\Delta| & 0 \\ 0 & -|\Delta| & h^*_k + \frac{2}{3} & -\zeta_k + \frac{2}{3} \\ |\Delta| & 0 & h^*_k + \frac{2}{3} & -\zeta_k + \frac{2}{3} \end{pmatrix} \Phi_k,$$
where \( \Phi_k^k = (a_{k,+}^\dagger, a_{k,-}^\dagger, a_{-k,-}^\dagger, a_{-k,+}^\dagger) \); the electron-impurity interaction is written as

\[
H_{\text{imp}} = \frac{1}{2} \sum_{k k'} \Phi_k^k V_{k-k'} \gamma_3 \Phi_{k'}^k.
\]  

(4)

We then transform the Hamiltonian in particle space to the quasiparticle one by using the transformation

\[
U_k = \begin{pmatrix}
    u_k & 0 & 0 & v_k \\
    0 & u_k & -v_k & 0 \\
    0 & v_k & u_k & 0 \\
    -v_k & 0 & 0 & u_k
\end{pmatrix}.
\]  

(5)

Here, \( u_k = \sqrt{\frac{1}{2} + \frac{k \cdot v}{2 \delta_k}} \) and \( v_k = \sqrt{\frac{1}{2} - \frac{k \cdot v}{2 \delta_k}} \). Then in the quasiparticle space, the field operator is denoted as \( \Psi_k = (\alpha_{k,+}, \alpha_{k,-}^\dagger, \alpha_{-k,-}^\dagger, \alpha_{-k,+}^\dagger)^T = U_k \Phi_k \). Accordingly, the BdG Hamiltonian in the quasiparticle space is written as

\[
H_0(k) = \begin{pmatrix}
    k \cdot \frac{v}{2} + \delta_k & \frac{k \cdot v}{2} h_k + h \Phi & -\frac{1}{\delta_k} h_k^* \\
    \frac{k \cdot v}{2} h_k^* + h \Phi & k \cdot \frac{v}{2} + \delta_k & 0 \\
    -\frac{1}{\delta_k} h_k & 0 & k \cdot \frac{v}{2} - \delta_k - \frac{k \cdot v}{2} h_k^* - h \Phi
\end{pmatrix}.
\]  

(6)

The electron-impurity interaction Hamiltonian is transformed to be

\[
H_{\text{imp}} = \frac{1}{2} \sum_{k k'} \Psi_k^T V_{k-k'}^\dagger \Psi_{k'},
\]  

(7)

where the impurity potential

\[
V_{k-k'}^\dagger = V_{k'-k} \begin{pmatrix}
    A_{kk'} & 0 & 0 & B_{kk'} \\
    0 & A_{kk'} & -B_{kk'} & 0 \\
    0 & -B_{kk'} & -A_{kk'} & 0 \\
    B_{kk'} & 0 & 0 & -A_{kk'}
\end{pmatrix},
\]  

(8)

with \( A_{kk'} = u_k u_{k'} - v_k v_{k'} \) and \( B_{kk'} = u_k v_{k'} + v_k u_{k'} \).

### III. SUPERCONDUCTING-VELOCITY–TUNABLE QUASIPARTICLE STATE IN QWs

In this section, we analyze the quasiparticle state in the superconducting QWs, which can be tuned by the superconducting velocity, first analytically (Sec. III.A) and then numerically (Sec. III.B).

#### A. Analytical analysis

In this part, we analytically analyze the quasiparticle state by using the equilibrium Green function at the Matsubara representation. In the derivation, the SOC is neglected as it is much weaker compared to the kinetic energy.

In the particle space, the equilibrium Green function at the Matsubara representation is defined as \( \hat{G}_{12} = \hat{G}_{12}^{\text{eq}} \hat{G}_{21}^{\text{eq}} \), in which \( \hat{G}_r \) represents the chronological product; \( (\cdot) \) is the imaginary-time–space point; \((\cdot)\) denotes the ensemble average; and \( \Phi(r, r) = e^{i\gamma M(r)/\hbar} \). The Green function in the frequency-momentum space is derived to be

\[
\hat{G} (i \omega_n, k) = \begin{pmatrix}
    A(i \omega_n, k) & 0 & 0 & C(i \omega_n, k) \\
    0 & -A(i \omega_n, k) & -C(i \omega_n, k) & 0 \\
    0 & C(i \omega_n, k) & B(i \omega_n, k) & 0 \\
    C(i \omega_n, k) & 0 & 0 & B(i \omega_n, k)
\end{pmatrix},
\]  

(9)

where

\[
\begin{align*}
A(i \omega_n, k) &= \frac{i \omega_n + \Phi_{k-\Phi_2}}{(i \omega_n + \Phi_{k-\Phi_2})(i \omega_n + \Phi_{k+\Phi_2}) - |\Delta|^2} \\
B(i \omega_n, k) &= \frac{i \omega_n - \Phi_{k-\Phi_2}}{(i \omega_n - \Phi_{k-\Phi_2})(i \omega_n + \Phi_{k+\Phi_2}) - |\Delta|^2} \\
C(i \omega_n, k) &= \frac{i \omega_n - \Phi_{k+\Phi_2}}{(i \omega_n + \Phi_{k-\Phi_2})(i \omega_n + \Phi_{k+\Phi_2}) - |\Delta|^2}
\end{align*}
\]  

(10)

Here, \( \omega_n = (2n+1) \pi k_B T \) are the Matsubara frequencies with \( n \) being integer and \( T \) representing the temperature. From this Green function, one obtains the particle density matrix at the equilibrium state,

\[
\rho^E(k) = \begin{pmatrix}
    \mathcal{A}(k) & 0 & 0 & \mathcal{C}(k) \\
    0 & \mathcal{A}(k) & -\mathcal{C}(k) & 0 \\
    0 & -\mathcal{C}(k) & \mathcal{B}(k) & 0 \\
    \mathcal{C}(k) & 0 & 0 & \mathcal{B}(k)
\end{pmatrix},
\]  

(11)

whose diagonal elements denote the electron and hole distributions, and the off-diagonal elements represent the anomalous correlations due to the superconducting order parameter. In Eq. (11),

\[
\begin{align*}
\mathcal{A}(k) &= \langle a_{k,+}^\dagger a_{k,+} \rangle \rangle = u^2_k f(E^+_k) + v^2_k f(E^-_k) \\
\mathcal{B}(k) &= \langle a_{-k,-}^\dagger a_{-k,-} \rangle \rangle = v^2_k f(E^+_k) + u^2_k f(E^-_k) \\
\mathcal{C}(k) &= \langle a_{k,+}^\dagger a_{-k,-} \rangle \rangle = u v_k f(E^+_k) - u v_k f(E^-_k)
\end{align*}
\]  

(12)

where \( f(E_k) = 1/(\exp[E_k/(\pi k_B T)] + 1) \) is the Fermi distribution function. For the quasiparticle, by a unitary transformation, the density matrix at the equilibrium state is

\[
\rho^E(k) = U_k \rho^E(k) U^\dagger_k = \text{diag} \left\{ f(E^+_k), f(E^+_k), f(E^-_k), f(E^-_k) \right\},
\]  

(13)

in which only the diagonal elements exist, denoting the quasi-electron and quasi-hole distributions.

From the quasiparticle distribution at the equilibrium state, one specific feature arises due to the modification of the energy spectrum by the superconducting velocity. It is noted that when \( v_s = 0, E^+_k \) and \( E^-_k \) is
always bigger (smaller) than zero. When $v_s \neq 0$, it can be found that when $m^* v_s^2 |\mu|/2 > |\Delta|^2$, there exist regions in which $E_k^+ < 0$ and $E_k^- > 0$ are satisfied. These regions are referred to as the blocking region because it is occupied by the quasi-electrons even at zero temperature.\cite{26,27} Specifically, the blocking region for the quasi-electron is written as

$$\begin{align} &\left\{ -\sqrt{m^* v_s^2 \mu} - |\Delta|^2 < \zeta_k - m^* v_s^2 \frac{2}{s} < \sqrt{m^* v_s^2 \mu} - |\Delta|^2 \right\} \\
&-1 \leq \cos \theta_k < \sqrt{\frac{\zeta_k + m^* v_s^2 / 8 |\Delta|^2}{m^* v_s^2 / 2 [\zeta_k + \mu]}} \end{align}$$

(14)

with $\theta_k$ being the angle between the momentum and superconducting velocity.

Finally, it is addressed that in the Fulde-Ferrell-Larkin-Ovchinnikov state,\cite{26,27} the Zeeman-field-induced center-of-mass momentum of Cooper pairs plays the similar role as the superconducting velocity here.

B. Numerical results

In this part, we present the numerical results for the properties of the quasiparticle state in GaAs QWs. All parameters including the band structure and material parameters used in our computation are listed in Table I.\cite{87,88} In the table, $n_e$ is the electron density, and $P_0$ represents the initial spin polarization.

| Parameter | Value |
|-----------|-------|
| $m^* / m_0$ | 0.067 |
| $n_e$ (cm$^{-2}$) | $10^{11}$ |

1. Blocking region

We first analyze the energy spectrum of the quasi-electron [Eq. (1)]. It is assumed that the superconducting velocity is small, which influences the superconducting state in the s-wave superconductor marginally.\cite{24,25} However, when $|\Delta| \ll |\Delta_S|$ here, it can efficiently tune the superconducting state in QWs. Without loss of generality, we assume that the superconducting velocity is along the x-direction. In Fig. 3, the $k_x$-dependencies of the energy spectra of the quasi-electron are plotted at different superconducting velocities. It can be seen from the figure that without the supercurrent (the red solid curve), the excitation energy is symmetric for $k_x > 0$ and $k_x < 0$. When there is finite superconducting velocity, the energy spectrum becomes tilted. Specifically, when $m^* v_s / k_F = 0.14$, $E_k^+ = 0$ can be realized, which is represented by the blue dashed curve; when $m^* v_s / k_F > 0.14$, there exist regions with $E_k^+ < 0$, as shown by the green chain curve when $m^* v_s / k_F = 0.5$. Here, $k_F$ is the Fermi momentum of the electron.

When $E_k^+ < 0$, the blocking region appears, which is determined by Eq. (14). When $v_s = 0.5 k_F / m^*$, the quasi-electron population at the equilibrium state is calculated [Eq. (13)], whose momentum dependence is plotted in Fig. 4(a). It can be seen from Fig. 4(a) that the blocking region is in the crescent shape, whose boundary constitutes the Fermi surface for the quasi-electron. Furthermore, it can be seen that in the Fermi surface, its left and right boundaries are contributed by the electron- and hole-like branches, respectively, in the shapes of arcs, referred to as Fermi arcs in the following. It is addressed that even though $|\Delta|$ is taken to the finite here, the basic pictures of the blocking region as well as the Fermi arcs remain the same as those revealed in Figs. I and II.

![FIG. 3](Color online) Energy spectra of the quasi-electron with different superconducting velocities $m^* v_s / k_F = 0$ (the red solid curve), 0.14 (the blue dashed curve) and 0.5 (the green chain curve). $|\Delta| = 0.5$ meV in the calculation. When $m^* v_s / k_F = 0$, the excitation energy is symmetric for $k_x > 0$ and $k_x < 0$. However, the finite superconducting velocity can cause the tilt of the energy spectrum. Specifically, when $m^* v_s / k_F \geq 0.14$, $E_k^+ \leq 0$ can be realized.

Actually, the electron distribution in the particle space is also significantly influenced due to the superconducting velocity [Eq. (13)], whose Fermi surface is no longer a circle, as shown in Fig. 4(b). It can be seen from Fig. 4(b) that a crescent region at $k_x > 0$ (labeled by “$A$”, enclosed by the dots) disappears and a new crescent region (labeled by “$B$”) emerges at $k_x < 0$. The modification of the electron distribution inevitably influences the anomalous correlations when there exists a supercurrent. In the presence of the supercurrent, there exist the anomalous correlations between the electron states with mo-
momentum $\mathbf{k} + \mathbf{q}/2$ and $-\mathbf{k} + \mathbf{q}/2$, which can be calculated from $\mathcal{C}(\mathbf{k})$ in Eq. (12). This indicates that the Cooper pairs carry the center-of-mass momentum $\mathbf{q}$, driven by the supercurrent. From the analysis of the electron distribution in Fig. (3b), one finds that the absence of the crescent region at $k_x > 0$ makes the electrons in the newly arising crescent region at $k_x < 0$ be unable to find their partners to constitute the Cooper pairs. Accordingly, there is no anomalous correlation for the electrons in the newly arising crescent region with $k_x < 0$ at zero temperature. The momentum dependence of the anomalous correlations without and with the superconducting velocity are explicitly shown in Figs. (3c) and (d). It can be seen from those two figures that only the electrons around the Fermi surface can have efficient anomalous correlations. Specifically, in Fig. (3c) without the supercurrent, all the electrons around the Fermi surface are paired. However, when $v_s = 0.5k_F/m^*$ in Fig. (3d), the blocking region appears, in which the anomalous correlation is suppressed to be close to zero at low temperature. Accordingly, the residue regions with anomalous correlations are suppressed to be very small when the superconducting velocity is large. This shows that the superconducting velocity provides an efficient way to tune the Cooper pairing in the superconducting QWs.

---

**FIG. 4:** (Color online) Momentum dependencies of the quasi-electron distribution [(a)], electron distribution [(b)], and anomalous correlations without [(c)] and with [(d)] the supercurrent. (a) is plotted in the quasiparticle space, whereas (b), (c) and (d) are shown in the particle space. In (a) and (b), $v_s = 0.5k_F/m^*$, $|\Delta| = 0.5$ meV in all the calculation. Specifically, in (a), the quasi-electron distribution is addressed, in which the blocking region in the crescent shape arises, whose boundary constitutes the “Fermi surface”. In (b), for the electron distribution, it is observed that a crescent region when $k_x > 0$ (labeled by “A”, enclosed by the dots) disappears and a new crescent region (labeled by “B”) appears when $k_x < 0$. In (c), we show the anomalous correlation without the supercurrent, in which all the electrons around the Fermi surface are paired. Finally, in (d), the anomalous correlation with the supercurrent ($v_s = 0.5k_F/m^*$) is presented. It can be seen that compared to (c), the regions with efficient anomalous correlations are suppressed to be very small.
2. Quasiparticle density

In this part, we show that the quasiparticle density in QWs can be efficiently tuned by the superconducting velocity. The quasiparticle density is calculated from the quasiparticle distributions in the presence of the superconducting velocity:

\[ n^q = \sum_k [f(E_{k\uparrow}^+) + f(E_{k\downarrow}^+)] \]  \hspace{1cm} (15)

In Fig. 5, the superconducting velocity dependence of the quasiparticle density with different order parameters \(|\Delta| = 0.5, 0.3, 0.2 \text{ and } 0.1 \text{ meV}\) are plotted by the blue dashed, yellow dashed, red solid and green chain curves. It is shown that with the increase of the superconducting velocity, the quasiparticle density first increases rapidly and then slowly, with the turning point corresponding to the appearance of the blocking region roughly. Specifically, with the increase of the quasiparticle density due to the superconducting velocity, the blocking region and the Fermi surface emerge. In this process, the system can experience the crossover between the non-degenerate and degenerate limits. Finally, it is noticed that when the superconducting velocity is large enough, the quasiparticle density is comparable to the one in the normal state.

![FIG. 5: (Color online) Superconducting velocity dependence of the quasiparticle density with different order parameters |Δ| = 0.5 meV (the blue dashed curve), 0.3 (the yellow dashed curve), 0.2 (the red solid curve) and 0.1 meV (the green chain curve). With the increase of the superconducting velocity, the quasiparticle density first increases rapidly and then slowly, with the turning point corresponding to the appearance of the blocking region approximately.](image)

3. Momentum current

In the presence of a finite superconducting velocity, the momentum current arises in the QW, which is calculated from the equilibrium density matrix,

\[ J = \sum_k 1/2 \text{Tr} \left\{ \tau_3 [U^\dagger_{k\uparrow}U_{k\downarrow}] + \frac{1}{2} (\tau_3 - 1) \right\} \odot \text{diag} \left\{ \mathbf{k} + \frac{\mathbf{q}}{2}, \mathbf{k} + \frac{\mathbf{q}}{2}, -\mathbf{k} + \frac{\mathbf{q}}{2}, -\mathbf{k} + \frac{\mathbf{q}}{2} \right\} \]  \hspace{1cm} (16)

Obviously, \( J_y = 0 \) when \( \mathbf{q} = q\hat{x} \). In Fig. 6 the superconducting-velocity dependencies of \( J_x \) are plotted with different order parameters \(|\Delta| = 0.5, 0.3 \text{ and } 0.2 \text{ meV}\). The unit for the momentum current is set to be \( J_0 = n_e k_F (k_B T/E_F) \) with \( E_F \) being the Fermi energy for the electron. It is shown that with the increase of the superconducting velocity, the momentum current first increases linearly and then decreases slowly, with the emergence of a peak. By defining the superconducting velocity corresponding to the peak of the current as the critical velocity, it can be seen that the critical velocity increases with the increase of the order parameter.

![FIG. 6: (Color online) Superconducting velocity dependence of the momentum current with different order parameters |Δ| = 0.5 (the blue dashed curve), 0.3 (the yellow dashed curve) and 0.2 meV (the red solid curve). The unit for the momentum current is set to be \( J_0 = n_e k_F (k_B T/E_F) \). The green chain curve shows the results calculated from Eq. (17) when |Δ| = 0.5 meV, which describes the behavior of momentum current with small superconducting velocity fairly well.](image)

We start our analysis from the case with small superconducting velocity (i.e., before the appearance of the blocking region). With small superconducting velocity satisfying \( k_s \cdot v_s \ll k_s^* \), the quasiparticle distribution function can be expanded as a series of \( v_s \). By keeping \( v_s \) to its linear order and considering \( |\Delta| \gg k_B T \) here, from Eqs. (11) and (16), the momentum current is calculated...
to be
\[ \mathbf{J}_x^a \approx m^* v_s \sum_k \left\{ u^2_k f(\delta_k) + \nu^2_k \left[ 1 - f(\delta_k) \right] \right\} + \sum_k k_x^2 v_s \frac{\partial f(\delta_k)}{\partial \delta_k} \approx m^* v_s \sum_k \nu^2_k. \] (17)

It is noted that \( \nu^2_k \) is just the distribution function of the Cooper pair condensate when \( v_s = 0 \) (e.g., refer to Takahashi et al\textsuperscript{28,74,75}), and hence here the momentum current is mainly carried by the Cooper pairs. The results calculated from Eq. (17) when \( |\Delta| = 0.5 \) meV is plotted by the green chain curve in Fig. 3 which almost coincides with the blue dashed curve when \( v_s \) is small. However, when the superconducting velocity is large, i.e., with the appearance of the blocking region, the current contributed from the Cooper pairs becomes significant. Specifically, the quasi-electron (quasi-hole) mainly populate with \( k_x < 0 \) (\( k_x > 0 \)). Therefore, from Eq. (16), the current contributed by the quasiparticles flows in the opposite direction to the one carried by the Cooper pairs. Accordingly, there exists the competition between the quasiparticles and Cooper pairs, leading to the critical velocity. Thus, the critical velocity can be estimated by \( \nu_c \approx \sqrt{2|\Delta|^2/(m^*\mu)} \), which just corresponds to the appearance of the blocking region.

IV. QUASIPARTICLE SPIN RELAXATION

In this section, we study the quasiparticle spin relaxation in the superconducting GaAs (100) QWs. We first derive the KSBEs for the quasiparticle in the quasiparticle approximation\textsuperscript{18,21,60–69} via the nonequilibrium Green function method with the generalized KadanoffBaym (KGB) ansatz\textsuperscript{9,89,90} (Sec. IV A), and then show the numerical results for the SRTs without (Sec. IV B 1) and with the supercurrent (Sec. IV B 2).

A. KSBEs

1. Derivation with full Hamiltonian

With a small Fermi energy in the semiconductor QWs, the derivation of the KSBEs is based on the quasiparticle approximation\textsuperscript{18,21,60–69,89}. In the quasiparticle space, the contour-ordered non-equilibrium Green function is defined as\textsuperscript{9,61,89}

\[ G_{12} = -i(T_\epsilon \Psi_1^\dagger \Psi_2) = \begin{pmatrix} G_{12}^{++} & G_{12}^{+-} \\ G_{12}^{−+} & G_{12}^{−−} \end{pmatrix}, \] (18)

which is an 8 × 8 matrix. Here, \( 1 = (t_1, r_1) \) represents the time-space point; \( T_\epsilon \) denotes the time contour; and \( \Psi(t, r) = (\alpha_1(t, r), \alpha_2(t, r), \alpha_3(t, r), \alpha_4(t, r))^T \) is the quasiparticle field operator. Specifically, \( G_{12}^{++} = -i(T_\epsilon \Psi_1 \Psi_2^\dagger), G_{12}^{−+} = G_{12}^{−−} = i(\Psi_2 \Psi_1^\dagger), G_{12}^{−+} = G_{12}^{−−} = -i(\Psi_1 \Psi_2^\dagger) \) and \( G_{12}^{++} = -i(T_\epsilon \Psi_1 \Psi_2^\dagger) \) with \( T_\epsilon \) and \( T_\epsilon \) representing the chronological ordering and anti-chronological ordering, respectively.

The contour-ordered Green function \( G_{12} \) satisfies the Gor’kov’s equations\textsuperscript{35,86}

\[ i \frac{\partial}{\partial t_1} - \hat{H}_0^\tau(\mathbf{k}_1) \right] G_{12} \right) \equiv \int d\Sigma_{13} G_{32}, \] (19)

\[ G_{12} \left[ -i \frac{\partial}{\partial t_2} - \hat{H}_0^\tau(-\mathbf{k}_2) \right] = \delta(1 - 2) \hat{\tau}_3 \left( \int d\Sigma_{13} G_{32} \right) \] (20)

Here, \( \hat{\tau}_3 = \text{diag}(1\times4, -1\times4) \), and \( \Sigma_{13} \) is the self-energy due to the quasiparticle-impurity interaction. Specifically, from Eqs. (19) and (20), one obtains the kinetic equations for \( G_{12}^{<} \),

\[ \left[ i \frac{\partial}{\partial t_1} - \hat{H}_0^\tau(\mathbf{k}_1) \right] G_{12}^{<} \equiv \int d3(\Sigma_{13} G_{32}^< + \Sigma_{31} G_{32}^A), \] (21)

\[ G_{12}^{<} \left[ -i \frac{\partial}{\partial t_2} - \hat{H}_0^\tau(-\mathbf{k}_2) \right] = \int d3(\Sigma_{13} G_{32}^< + \Sigma_{31} G_{32}^A) \] (22)

where “R” and “A” label the retarded and advanced Green functions\textsuperscript{61–63,66–89}.

By defining \( (t, r) = (t_1 - t_2, r_1 - r_2) \) and \((\mathbf{R}, T) = (t_1 + t_2, r_1 + r_2)/2 \) and then taking the difference of Eqs. (21) and (22), one obtains

\[ i \partial_T G_{12}^{<} - \left[ \hat{H}_0^\tau(\mathbf{k}_1) G_{12}^{<} - G_{12}^{<} \hat{H}_0^\tau(-\mathbf{k}_2) \right] \]

\[ = \int d3(\Sigma_{13} G_{32}^< + \Sigma_{31} G_{32}^A - \Sigma_{13} G_{32}^R - \Sigma_{31} G_{32}^A). \] (23)

From Eq. (23), by using the gradient expansion\textsuperscript{89}, the kinetic equation is derived for the Fourier component of \( G_{12}^{<} \), i.e., \( G^{<}(\mathbf{R}, T; \mathbf{k}, E) = \int dt \text{e}^{iE t - i\mathbf{k} \cdot \mathbf{r}} G^{<}(\mathbf{R}, T; \mathbf{r}, t) \), which is written as
Here, [ ] and { } represent the commutator and anti-commutator, respectively; \( \Sigma^\pm_\alpha (\mathbf{k}; t_1, t_3) \) is the detailed balance is automatically satisfied. We neglected. This approximation has been well applied in the quasiparticle annihilation (creation) to (from) the approximate, we derive the scattering term, the GKB ansatz and Markovian approximation are used.\(^{9,89,90}\) Specifically, in the BdG Hamiltonian \([\text{Eq. (6)}]\) and quasiparticle-netic equation, we neglect the off-diagonal \(2 \times 2\) blocks in \( H_0^\alpha (\mathbf{k}) \) can break the quasiparticle number conservation because of the precession between the quasi-electron and quasi-hole. This is not strange because in \( H_0^\alpha (\mathbf{k}) \), the quasiparticle number operator does not commute with the BdG Hamiltonian (also the electron-impurity interaction Hamiltonian) because of the terms proportional to \( \alpha a \alpha S^\dagger \) and \( \alpha^\dagger \alpha S^\dagger \). Here, \( S \) and \( S^\dagger \) are the annihilation and creation operators for the Cooper pairs.\(^{18,79-81}\) Specifically, these terms are related to the annihilation or creation of two quasiparticles to create or annihilate one Cooper pair.\(^{18,72-81}\)

Nevertheless, it suggests that when the process for the quasiparticle annihilation (creation) to (from) the Cooper pair condensate is slow compared to the process under investigation, the part violating the quasiparticle number conservation in the full Hamiltonian can be neglected. This approximation has been well applied in the derivation of the quasiparticle kinetic equation (e.g., Refs.\(^{18,54-64}\)). Fortunately, once the Hamiltonian violating the quasiparticle number conservation is neglected, the detailed balance is automatically satisfied. We address that this assumption is reasonable for the weak SOC and low impurity density in this investigation.

The violation of the detailed balance and quasiparticle number conservation can also be understood from the mathematical point of view. It is noted that the Gor’kov space spanned by the “electron” and “hole” bands is larger than the real physical space. For linear operations on the Green function, no consequence will occur. However, for nonlinear operations, unphysical consequence may appear.

2. KSBEs with detailed balance and quasiparticle number conservation satisfied

From the above analysis, to obtain a self-consistent kinetic equation, we neglect the off-diagonal \(2 \times 2\) blocks in both the BdG Hamiltonian \([\text{Eq. (6)}]\) and quasiparticle-impurity interaction Hamiltonian \([\text{Eq. (7)}]\). To further derive the scattering term, the GKB ansatz and Markovian approximation are used.\(^{9,89,90}\) Specifically, in the GKB ansatz,\(^{9,89,90}\)

\[
G^\ge_\alpha (\mathbf{R}; \mathbf{k}; t_1, t_2) = \mp \left[ G^R_\alpha (\mathbf{R}; \mathbf{k}; t_1, t_2) \rho^\ge_\alpha (\mathbf{R}; \mathbf{k}; t_2) \\
- \rho^\ge_\alpha (\mathbf{R}; \mathbf{k}; t_1) G^A_\alpha (\mathbf{R}; \mathbf{k}; t_1, t_2) \right],
\]

where \( \rho^\ge_\alpha (\mathbf{R}; \mathbf{k}; t) = -i \int dE / (2\pi) G^\ge_\alpha (\mathbf{R}; \mathbf{k}; t, E) \). In Eq. \( 25 \), \( G^R_\alpha (\mathbf{R}; \mathbf{k}; t_1, t_2) \) and \( G^A_\alpha (\mathbf{R}; \mathbf{k}; t_1, t_2) \) are further approximated by their free equilibrium forms, written as

\[
G^R(\mathbf{R}; \mathbf{k}; t_1, t_2) \approx -i \theta(t_1 - t_2) \exp \left[ -i(t_1 - t_2) H_0^\alpha (\mathbf{k}) \right] \tag{26}
\]

\[
G^A(\mathbf{R}; \mathbf{k}; t_1, t_2) \approx i \theta(t_2 - t_1) \exp \left[ -i(t_1 - t_2) H_0^\alpha (\mathbf{k}) \right]. \tag{27}
\]

Here, \( \theta(x) \) is the Heaviside step function, and \( H_0^\alpha (\mathbf{k}) \) does not include the off-diagonal \(2 \times 2\) blocks. In the Markovian approximation,\(^{9,89,90}\)

\[
\rho^\ge_\alpha (\mathbf{R}; \mathbf{k}; t_3) = \exp \left[ i H_0^\alpha (\mathbf{k})(t_1 - t_3) \right] \rho(\mathbf{R}; \mathbf{k}; t_1) \times \exp \left[ -i H_0^\alpha (\mathbf{k})(t_1 - t_3) \right]. \tag{28}
\]

Furthermore, due to the small SOC, its contribution to the second and third terms in the left and right-hand sides of Eq. \( 24 \) can be neglected.\(^{9,89,90}\)

Finally, by taking \( t_1 \to t_2 \), i.e., \( t \to 0 \), from the \( E \)-integrated Green function, one obtains the KSBEs of the quasiparticle,

\[
\frac{\partial \rho^h_\alpha}{\partial T} + \left( \frac{\mathbf{v}_s + \mathbf{c}_k}{\mathbf{k}} \mathbf{s}_k - i \gamma \right) \frac{\partial \rho^h_\alpha}{\partial \mathbf{R}} + \mathbf{c}_k \left[ \frac{\partial \mu(\mathbf{R})}{\partial \mathbf{R}} \right] \tau_3 \frac{\partial \rho^h_\alpha}{\partial \mathbf{k}} + i \left[ \begin{array}{cc} h^s_\alpha (\mathbf{k}) & 0 \\
0 & h^h_\alpha (\mathbf{k}) \end{array} \right] \rho^h_\alpha = -2\pi n_i \sum_{\mathbf{k}'} |V^{\text{eff}}_{\mathbf{k} - \mathbf{k}'}|^2
\]

\[
\times \left[ \delta(E^+_{\mathbf{k}} - E^-_{\mathbf{k}'}) \frac{1 + \tau_3}{2} (\rho^h_{\mathbf{R}^+} - \rho^h_{\mathbf{R}^-}) + \delta(E^+_{\mathbf{k}' - \mathbf{k}} - E^-_{\mathbf{k}}) \frac{1 - \tau_3}{2} (\rho^h_{\mathbf{R}^+} - \rho^h_{\mathbf{R}^-}) \right], \tag{29}
\]

where

\[
|V^{\text{eff}}_{\mathbf{k} - \mathbf{k}'}|^2 = |V_{\mathbf{k} - \mathbf{k}'}|^2 (u_k u_{k'} - v_k v_{k'})^2, \tag{30}
\]

\[
h^s_\alpha (\mathbf{k}) = \left( \begin{array}{cc} 0 & \frac{\mathbf{c}_k}{\mathbf{s}_k} h_k + \mathbf{s}_k \\
\frac{\mathbf{c}_k}{\mathbf{s}_k} h_k - \mathbf{s}_k & 0 \end{array} \right), \tag{31}
\]

\[
h^h_\alpha (\mathbf{k}) = \left( \begin{array}{cc} 0 & \frac{\mathbf{c}_k}{\mathbf{s}_k} h_k - \mathbf{s}_k \\
\frac{\mathbf{c}_k}{\mathbf{s}_k} h_k + \mathbf{s}_k & 0 \end{array} \right). \tag{32}
\]

In this investigation at extremely low temperature, the quasiparticle-quasiparticle and quasiparticle-phonon interactions are inefficient and hence only the quasiparticle-impurity scattering is presented here. One notes that when the SOC and \( \mathbf{v}_s \) are taken to be zero, Eq. \( 24 \) can recover the traditional Boltzmann-like equation for the quasiparticle.\(^{15,28,54,60-64}\) Moreover, when \( |\Delta| \) and \( \mathbf{v}_s \) are taken to be zero, Eq. \( 24 \) can also recover the conventional KSBEs for electrons.\(^{2}\)
In Eq. (29), the second, third and fourth terms correspond to the diffusion, drift and coherence terms, respectively. Their physical origins are clear from the point of view that the quasiparticle state is the combination of the electron and hole ones [Eq. (5)]. Specifically, for the diffusion term, one notes that the group velocities for the quasi-electron and quasi-hole are \( \frac{V_d}{2} + \frac{\epsilon_k}{\delta_k m} \) and \( \frac{V_d - \epsilon_k k}{\delta_k m} \), respectively, which correspond to the quasiparticle velocities in Eq. (29). For the drift term, it can be seen that the charges for the quasi-electron and quasi-hole are \( -|e|(u_k^2 - v_k^2) = -|e|\epsilon_k/\delta_k \) and \(|e|\epsilon_k/\delta_k\), respectively, which are just responsible for the electrical force experienced by the quasiparticle under the electrical field. Finally, for the coherence term, the SOC experienced by the quasi-electron [Eq. (32)] is the combination of the ones experienced by the electron and hole, which can be calculated from

\[
h_{soc}^e(k) = u_k^2 \begin{pmatrix} 0 & h_{k+\frac{3}{2}} \hbar \\ \frac{h_{k+\frac{3}{2}}}{2} & 0 \end{pmatrix} + \epsilon_k^2 \begin{pmatrix} 0 & -h_{k-\frac{3}{2}} \hbar \\ -h_{k-\frac{3}{2}} \hbar & 0 \end{pmatrix}.
\]  

(33)

B. Numerical results

In this part, we study the quasiparticle spin relaxation in the spatially homogeneous system. By numerically solving the KSBEs [Eq. (29)], one obtains the SRT from the time evolution of the spin polarization

\[
S(t) = \sum_k \frac{1}{4n_q} \text{Tr} \left\{ \tau_3 \left[ \rho_k^e(t) + \frac{1}{2}(\tau_3 - 1) \right] \text{diag}(\sigma, -\sigma) \right\},
\]

(34)

where \( \sigma \) are the Pauli matrices. Here, we focus on the situation that the initial spin polarization of the quasiparticle is along the \( \hat{z} \)-direction, corresponding to the spin imbalance, which can be realized by the spin injection with small charge imbalance.\(^{18,20,22-29,31,32}\) Accordingly, the initial density matrix for the quasiparticle is written as

\[
\rho_k^e(t = 0) = \text{diag} \left[ f(E_{k+1}^+), f(E_{k+1}^-), f(E_{k-1}^+), f(E_{k-1}^-) \right],
\]

(35)

where \( f(E_{k+1}^\pm) = f(E_{k+1}^\pm + \mu_k^2) \) and \( f(E_{k-1}^\pm) = f(E_{k-1}^\pm + \mu_k^2) \). Here, \( \mu_k^2 \) and \( \mu_k^2 \) are determined by the density of quasi-electrons with spin-up \( n_{1,1}^q \) and spin-down \( n_{1,1}^q \), i.e.,

\[
n_{1,1}^q = \sum_k f(E_{k,1,1}^+) = \sum_k f(E_{k,1,1}^+) + \mu_k^2, 
\]

(36)

The parameters for the computation are listed in Table[II].

1. Quasiparticle spin relaxation without a supercurrent

In this part, we analyze the quasiparticle spin relaxation without the supercurrent, i.e., \( v_s = 0 \), and reveal the influence of the magnitude of the order parameter on the quasiparticle spin relaxation. When \( |\Delta| = 0 \), the system returns to the normal situation with the Rashba-like SOC, which has been well studied in GaAs (100) QWs\(^{20-29,32}\). In Fig. 7 it is shown that when \( n_i \lesssim 0.05n_e \) (\( n_i \gtrsim 0.05n_e \)), the system lies in the weak (strong) scattering regime with \( \tau_s \propto \tau_N \propto (\tau_N^{-1})^{-1} \). Here, \( \tau_N \) is the momentum relaxation time in the normal state. When \( |\Delta| \) varies from 0.1 to 0.5 meV, the SRTs are enhanced in both the weak and strong scattering regimes. However, the boundary between the weak and strong scattering regimes is unchanged. This can be understood from the following analytical analysis.

\[
\text{FIG. 7: (Color online) Impurity density dependence of the quasiparticle SRTs without the supercurrent when } |\Delta| = 0 \text{ (normal state, the red solid curve with squares), 0.1 (the yellow dashed curve with circles), 0.3 (the green chain curve with squares) and 0.5 meV (the blue dashed curve with crosses). In no matter the weak or strong scattering regime, the SRTs are enhanced in the superconducting state compared to the normal one.}
\]

From Eq. (29), one can see that when \( v_s = 0 \), both the SOC and momentum scattering for the quasiparticle are modified by the order parameter. Specifically, from the coherent term [the fourth term in Eq. (29)], one observes that when \( v_s = 0 \), the SOC is modified to be

\[
h_{soc}^e(k) = (\epsilon_k/\delta_k)h_{soc}^N(k),
\]

(37)

where \( h_{soc}^N(k) \) is the normal-state SOC in GaAs (100) QW. Accordingly, due to the factor \( \epsilon_k/\delta_k \) in Eq. (37), the SOC is exactly zero when \( |k| = k_F \) and efficiently suppressed for the quasiparticles with momentum around \( k_F \). For the scattering term, new features arise due to the modifications of the quasiparticle-impurity interaction potential [Eq. (30)] and the DOS. In the quasiparticle-impurity potential [Eq. (31)], the coherent factor \( (u_k u_{k'}) -
\[ \tau_k^S = \left( \epsilon_k / |\epsilon_k| \right)|\tau_k^N|. \]  

(38)

Because at low temperature, the quasiparticles mainly populate around the states with momentum \( |k| = k_F \), the momentum scattering is efficiently suppressed in the superconducting state.

Obviously, from Eqs. (37) and (38), \( |h_{soc}(k)|^2 = |h_{soc}^N(k)|^2 \), and hence the boundary between the weak and strong scattering regimes remains unchanged when the system enters to the superconducting state. Then by solving the KSBEs analytically, one obtains the SRTs in both the strong and weak scattering regimes.\(^{29,32}\) Specifically, in the strong scattering limit with \( \Omega_{k,k'}^S \ll 1, S_k(t) \approx P_0 \exp[-4(\Omega_k^S)^2 \tau_k^S t] \). Here,

\[ \Omega_k^S = (\alpha k)(c_k / \delta_k) = \Omega_k^N (c_k / \delta_k) \]  

(39)

is the precession frequency due to the SOC, and

\[ \frac{1}{\tau_k^S} = \frac{n \mu^*}{2 \pi} |c_k| \int d\theta_{k-k'} |V_{k-k'}|^2 (1 - \cos \theta_{k-k'}) \]  

(40)

In the weak scattering limit with \( \Omega_{k,k'}^S \gg 1, S_k(t) \approx P_0 \exp[-t/(2\tau_{k,k'}^S)] \cos(2\Omega_{k,k'}^S t) \). On one hand, the momentum scattering opens a spin relaxation channel due to the factor \( \exp[-t/(2\tau_{k,k'}^S)] \); on the other hand, the factor \( \cos(2\Omega_{k,k'}^S t) \) can cause the free induction decay due to different precession frequency with different momentum, which is suppressed in the degenerate regime.\(^{29,32}\) Accordingly, the SRT for the quasiparticle with momentum \( k \) reads

\[ \tau_k^S (k) \approx \begin{cases} 4(\Omega_k^S)^2 \tau_k^S, & \Omega_{k,k'}^S \ll 1; \\ 2\tau_k^S, & \Omega_{k,k'}^S \gg 1 \end{cases} \]  

(41)

with \( \tau_k^S (k) \) being the SRT in the normal state. Due to the factor \( c_k / |c_k| \) in Eq. (12), no matter in the strong or weak scattering regime, the SRT for the quasiparticle with the momentum around \( k_F \) is enhanced compared to the normal one.

Finally, based on Eq. (12), we calculate the total SRT of the quasiparticle, written as\(^{34,35}\)

\[ \frac{1}{\tau_s} = \sum_k \frac{1}{\tau_k^N (k)} \frac{|c_k|}{\delta_k} \left[ f(E_{k\uparrow}) - f(E_{k\downarrow}) \right] \]  

(43)

With the small spin polarization, the spin polarization is limited to the region around the Fermi surface, and hence in Eq. (43), \( \tau_k^N (k) \approx \tau_k^N (k_F) \). Accordingly, from Eq. (43), one obtains

\[ \frac{1}{\tau_s} \approx \frac{1}{\tau_s^N} \frac{1}{P_0 \hbar q} \frac{m^*}{2\pi} (\mu_1^2 - \mu_2^2) f(\sqrt{\mu^2 + |\Delta|^2} - 2f(|\Delta|)). \]  

(44)

Furthermore, when \( \mu \gg |\Delta| \) and \( \mu \approx -\mu^2 \equiv \delta \mu \) due to the small spin polarization, one obtains

\[ \frac{1}{\tau_s} \approx \frac{1}{\tau_s^N} \frac{1}{P_0 \hbar q} \frac{2m^*}{\pi} |\delta \mu| f(|\Delta|) = Q \frac{1}{\tau_s^N}. \]  

(45)

with \( Q \equiv \frac{1}{P_0 \hbar q} \frac{2m^*}{\pi} |\delta \mu| f(|\Delta|) \). Here, with \( |\Delta| = 0.1, 0.3 \) and 0.5 meV, \( 1/Q \) is calculated to be 1.7, 2.7, and 3.3, in good agreement with the numerical results. From Eq. (45), this shows that due to the order parameter, the SRT can be enhanced by several times and increases with the increase of the order parameter.

Finally, it is addressed that we also consider the influence of the inelastic quasiparticle-quasiparticle scattering on the quasiparticle spin relaxation, which is proven to be inefficient even with the low impurity density \( n_i = 10^{-3} n_e \).\(^{93}\)

### 2. Quasiparticle spin relaxation with a supercurrent

In this part, we consider the influence of the supercurrent or superconducting velocity on the quasiparticle spin relaxation with small and large order parameters \( |\Delta| = 0.01 \) and 0.5 meV, respectively. The superconducting velocity can cause the tilt of the quasiparticle energy spectrum and hence modifies the quasiparticle distribution (refer to Sec. III B 1), which is expected to cause rich physics in the quasiparticle spin relaxation. It is assumed that the condensation process associated with the annihilation of the quasi-electron and quasi-hole is slow compared to the spin relaxation rate. Here, we first describe the rich phenomenom from the impurity density and superconducting velocity dependencies of the quasiparticle SRTs.

Specifically, in Figs. S(a) and (b), the impurity density dependencies of the SRTs are plotted with different superconducting velocities \( v_s = 0 \) (the red solid curve with squares), 0.1\( k_F / m^* \) (the blue dashed curve with diamonds) and 0.5\( k_F / m^* \) (the green chain curve with circles). In Fig. S(a), with an extremely small order parameter \( |\Delta| = 0.01 \) meV, it can be seen that in the weak (strong) scattering limit, the SRT can be enhanced (suppressed) by the superconducting velocity when \( v_s \lesssim 0.5k_F / m^* \). Moreover, with the increase of the superconducting velocity, the boundary between the weak and strong scattering regimes remains unchanged. Anomalously, when the system enters into the strong scattering regime, for \( v_s > 0.1k_F / m^* \), the SRT becomes insensitive to the momentum scattering. However, when
the order parameter is large enough with $|\Delta| \gtrsim 0.1$ meV, the behaviors of the SRT become different. Specifically, it can be seen from Fig. 8(b) that when $|\Delta| = 0.5$ meV, in the weak (strong) scattering regime, the SRT can be either enhanced or suppressed (suppressed) by the superconducting velocity. In particular, for the superconducting velocity $v_s = 0.1k_F/m^*$, the boundary between the weak and strong scattering regimes is shifted, which arises at the larger impurity density and remains unchanged with the further increase of the superconducting velocity (e.g., $v_s = 0.5k_F/m^*$).

![Graphs showing SRT dependencies](image)

**FIG. 8:** (Color online) Impurity density [(a) and (b)] and superconducting velocity [(c) and (d)] dependencies of the SRTs. In (a) and (c) [(b) and (d)], $|\Delta| = 0.01$ (0.5) meV. Specifically, in (a) and (b), the SRTs are plotted with different superconducting velocities $v_s = 0$ (the red solid curve with squares), $0.1k_F/m^*$ (the blue dashed curve with diamonds) and $0.5k_F/m^*$ (the green chain curve with circles). In (c) and (d), the SRTs are presented with different impurity densities $n_i/n_e = 0.005$ (the red solid curve with squares) and 1 (the blue dashed curve with squares). Finally, with the branch-mixing scattering removed, in (c) and (d), the SRTs are shown by the cyan (yellow) dashed curve with crosses (circles) when $n_i/n_e = 0.005$ (1).

To see the role of the superconducting velocity on the quasiparticle spin relaxation more clearly, we further calculate the superconducting velocity dependencies of the SRTs with different impurity densities, shown in Figs. 8(c) and (d) at low and high impurity densities with $|\Delta| = 0.01$ and 0.5 meV. Specifically, in Fig. 8(c), one finds that when the order parameter is extremely small ($|\Delta| = 0.01$ meV), with the increase of the superconducting velocity, in the weak scattering regime with $n_i/n_e = 0.005$, the SRT first increases and then becomes insensitive to the superconducting velocity; whereas in the strong scattering regime, the SRT first decreases rapidly and then increases. However, when the order parameter becomes larger (with $|\Delta| \gtrsim 0.1$ meV), the re-
spins of the SRTs to the superconducting velocity also becomes very different. Specifically, it can be seen from Fig. 4(d) that when $|\Delta| = 0.5$ meV, with the increase of the superconducting velocity, the SRT in the weak scattering regime ($n_s/n_e = 0.005$) first increases, then decreases and finally becomes insensitive to the superconducting velocity; whereas in the strong scattering regime ($n_s/n_e = 1$), the SRT decreases monotonically.

Before detailed explanation for the rich behaviors of the quasiparticle spin relaxation in the impurity density and superconducting velocity dependencies, we first address two important influences of the superconducting velocity on the quasiparticle state. On one hand, when there exists the supercurrent, as addressed in Sec. III B 1 that the quasiparticle energy spectrum is tilted by the superconducting velocity, and hence the blocking region can appear. Around the blocking region, the quasiparticle Fermi surface emerges, which is constituted by the electron- and hole-like Fermi arcs (refer to Figs. 1 and 2). On the other hand, only when $|\Delta| \gtrsim 0.1$ meV, due to the superconducting velocity, the branch-mixing scattering can be efficiently triggered due to the tilt of the energy spectrum (refer to Fig. 2). When $|\Delta| \to 0$, the branch-mixing scattering is forbidden due to the coherence prefactor $(\approx e_k/[e_k + e_{k'}])$ tends to zero in the momentum scattering [Eq. (20)].

a. Quasiparticle spin relaxation in a Fermi arc

We first analyze the quasiparticle spin relaxation with extremely small order parameters $(|\Delta| \ll 0.1$ meV). As addressed above, the branch-mixing scattering for the quasiparticle is forbidden, indicating that the electron- and hole-like Fermi arcs are independent when the condensation process is slow enough. When $v_s \gtrsim 0.1 k_F/m^*$, the quasiparticle distribution enters into the degenerate regime (refer to Fig. 5), and the thermal excitations of the quasiparticles happen around the Fermi arcs. In this situation, the quasiparticle spin relaxation can be simply understood by only analyzing the Fermi arc. Specifically, the angular-average of the effective magnetic field in one Fermi arc, i.e., $(\Omega_k)_a$, is not zero. By writing the effective magnetic field as $\Omega_k = (\Omega_k - (\Omega_k)_a) + (\Omega_k)_a$, one finds that around one Fermi arc, $\Omega_k$ plays the role of the effective magnetic field (inhomogeneous broadening) and $(\Omega_k)_a$ acts as an effective Zeeman field. Specifically, at low temperature, the effective Zeeman field can cause the spin oscillations even in the strong scattering regime (refer to Appendix A).

Moreover, when $(\Omega_k)_a$ is comparable to $|\Omega_k|$, $(\Omega_k)_a$ plays marginal role on the spin relaxation, whereas $|\Omega_k|$ leads to the spin relaxation. In particular, one finds that the magnitude of $|\Omega_k|$ strongly depends on the direction of the momentum. Accordingly, around one Fermi arc, the variation of momentum direction can cause the variations of both the direction and magnitude of the effective magnetic field, acting as the angle-dependent and module-dependent inhomogeneous broadenings, respectively. In this situation, even due to the elastic scattering, the module-dependent inhomogeneous broadening is triggered which is enhanced by the momentum scattering. Nevertheless, the motional narrowing effect can suppress the spin relaxation in the strong scattering regime. Thus, the competition of the two trends leads to the insensitiveness of momentum scattering dependence of the SRT in the strong scattering regime. The above features for the spin relaxation in the strong scattering regime actually provide a method for experimentally verifying the existence of the Fermi arc.

The Fermi arc structure also influences the quasiparticle spin relaxation in the weak scattering regime. By assuming that the proportions of the spin polarization carried by the electron- and hole-like branches are $P_e$ and $1 - P_e$, respectively. Then, due to the separations of the electron-like (hole-like) Fermi arc, the angular-averaged effective magnetic field magnitude is estimated to be $(|\Omega_k|)_a \approx P_e|\Omega_k| [(1 - P_e)|\Omega_k|]$, and the momentum scattering time becomes $\tau_k' \approx \tau_k^N/P_e |\Omega_k|^N/(1 - P_e)$. Obviously, $(|\Omega_k|)_a \tau_k' \approx |\Omega_k|_k$, and hence the boundary between the weak and strong scattering regimes remains unchanged in the presence of the supercurrent. Moreover, with $P_e$ around $1/2$, the angular-average of the momentum scattering time can be estimated by $(\tau_k') = P_e(\tau_k^N/P_e) + (1 - P_e)\tau_k^N/(1 - P_e) = 2\tau_k^N$. Then when $v_s \gtrsim 0.1 k_F/m^*$, the SRT in the weak scattering regime is enhanced to be two times of the one with $v_s = 0$, which agrees with the numerical calculation in Figs. 8(a) and (c) fairly well. It is emphasized that these estimations are based on the Fermi arcs, which are only established when $v_s \gtrsim 0.1 k_F/m^*$.

Facilitated with these understandings, we then analyze the superconducting velocity dependencies of the SRT, explicitly shown in Fig. 5(c). When the superconducting velocity is small ($v_s \lesssim \approx 0.1 k_F/m^*$), there still exists considerable quasiparticle population in the region with $k_x > 0$. In this situation, the momentum scattering time increases from $\tau_k^N$ to $2\tau_k^N$ with the increase of the superconducting velocity. Hence, in the weak (strong) scattering regime, the SRT increases (decreases) with the increase of the superconducting velocity. Whereas when $v_s \gtrsim 0.1 k_F/m^*$, the physics can be simply understood based on the Fermi arc as addressed. Accordingly, in the weak scattering regime, the SRT becomes two times of the one with $v_s = 0$, and remains unchanged with the increase of the superconducting velocity.

In the strong scattering regime, with the increase of the superconducting velocity, $(\Omega_k)_a$ decreases, and the module-dependent inhomogeneous broadening is suppressed. Hence, with the momentum scattering time relatively unchanged, the SRT in the strong scattering regime increases with the increase of the superconducting velocity.

b. Branch-mixing-induced spin relaxation channel

We then focus on the quasiparticle spin relaxation with finite order parameter $(|\Delta| \gtrsim 0.1$ meV). We first explain the shift of the boundary between the weak and strong scattering regimes due to the superconducting velocity when $|\Delta| = 0.5$ meV [Fig. 5(b)]. It is noticed that when
$|\Delta| = 0.5$ meV with $v_s = 0$, from Eq. 67, one finds that the SOC around the Fermi momentum is markedly suppressed for the quasiparticles. Due to the supercurrent, before the blocking region appears ($v_s \lesssim 0.14k_F/m^*$), the quasiparticle populations are shifted away from the Fermi momentum. This enhances not only the inhomogeneous broadening but also the momentum scattering time due to the suppression of the phase space available for the quasiparticle scattering. Thus, when $v_s = 0.1k_F/m^*$, these two responses to the supercurrent jointly lead to the shift of the boundary between the weak and strong scattering regimes to a larger impurity density. Nevertheless, once the blocking region forms (e.g., $v_s = 0.5k_F/m^*$), the influence of the superconducting velocity on the boundary between the weak and strong scattering regime is similar to the case with extremely small order parameter addressed above. Thus, when $v_s = 0.5k_F/m^*$ in Fig. 8(d), the boundary between the weak and strong scattering regimes remains unchanged.

We then analyze the superconducting velocity dependencies of the SRTs, shown in Fig. 8(d). Unlike the situation with an extremely small order parameter, the branch-mixing scattering can be efficiently triggered in the presence of the blocking region. Here, the role of the branch-mixing scattering on the quasiparticle spin relaxation is revealed by comparing the SRTs with and without the branch-mixing scattering. In Fig. 8(d), with the branch-mixing scattering switched off, in the strong (weak) scattering regime, it is shown by the yellow (cyan) dashed curve with circles (crosses) that the SRTs are much larger than (comparable to) the ones with the branch-mixing scattering when $v_s \gtrsim 0.14k_F/m^*$. Hence, the branch-mixing scattering plays a dominant (marginal) role on the quasiparticle spin relaxation in the strong (weak) scattering regime in the presence of the blocking region. It is noted that the spin relaxation channel due to the branch-mixing scattering resembles the one due to the inter-valley scattering shown in our previous studies on the electron spin relaxations in monolayer ripple graphene and monolayer MoS$_2$.

Finally, we address a new feature in the weak scattering regime when $|\Delta| = 0.5$ meV compared to the case with extremely small order parameter $|\Delta| = 0.01$ meV. In Fig. 8(d), one notices that when $|\Delta| = 0.5$ meV with $n_i/n_a = 0.005$, with the increase of the superconducting velocity in the region $0.1k_F/m^* \lesssim v_s \lesssim 0.3k_F/m^*$, the SRT is suppressed. This suppression of the SRT comes from the quasiparticle density dependencies on the superconducting velocity (refer to Fig. 8). When $0.1k_F/m^* \lesssim v_s \lesssim 0.3k_F/m^*$, the system lies in the crossover between the non-degenerate and degenerate limits. As predicted in the Brooks-Herring formula in the non-degenerate regime, the momentum scattering due to impurities is enhanced with the increase of the quasiparticle density, owing to the increase of the phase space available for the quasiparticle scattering; whereas in the degenerate regime, the quasiparticle-impurity scattering becomes insensitive to the quasiparticle density. Hence, when $v_s \gtrsim 0.1k_F/m^*$, the SRT first decreases and then becomes unchanged with the increase of the superconducting velocity.

V. CONCLUSION AND DISCUSSION

In conclusion, we have investigated the DP spin relaxation for the quasiparticle with a novel superconducting-velocity–tunable state in GaAs (100) QWs in proximity to an s-wave superconductor, by the KSBEs derived in the quasiparticle approximation. In the superconducting QW, the superconducting velocity induced from the superconducting phase is shown to cause the tilt of the quasiparticle energy spectrum. It is found that when the quasiparticle energy spectrum is tilted to be smaller than the chemical potential, a blocking region corresponding to the negative excitation energy appears, which is in the crescent shape. The existence of the blocking region can significantly influence the Cooper pairings, quasiparticle density and momentum current in QWs.

Specifically, the center-of-mass momentum $q$ is carried by the Cooper pairs, with the anomalous correlations only existing between the states with momentum $k+q/2$ and $-k+q/2$. Moreover, the Cooper pairings around the electron Fermi surface are efficiently suppressed. Furthermore, the quasiparticle density increases with the increase of the superconducting velocity. Particularly, the degenerate regime can be realized and the Fermi surface around the blocking region for the quasiparticles appears. The quasiparticle Fermi surface is constituted by the electron- and hole-like Fermi arcs. Finally, it is revealed that when the blocking region appears, the momentum current contributed by the quasiparticles flows in the opposite direction to the one carried by the Cooper pairs. Thus, in the superconducting velocity dependence of the momentum current, a peak arises due to the competition of the Cooper pairs and quasiparticles in the blocking region, whose appearance corresponds to the emergence of the blocking region.

We then study the DP spin relaxation for the quasiparticles in the superconducting QWs by the KSBEs. The KSBEs for the quasiparticle are set up based on the quasiparticle approximation, in which the SOC and quasiparticle-impurity scattering are explicitly considered. By using the KSBEs, the SRTs without and with the supercurrent are calculated. Rich physics is revealed. Without the supercurrent, we address that the branch-mixing scattering due to the impurity is forbidden, indicating that the electron- and hole-like branches are independent and hence only the intra-branch spin relaxation channel exists. In this situation, when $|\Delta|$ tends to zero, the SRT recovers to the normal one. Whereas with finite order parameter, we find that compared to the normal state, both the SOC and quasiparticle-impurity scattering are efficiently suppressed due to the same coherence factor $|\epsilon_k|/\Delta_k$. This leads to the enhancement of the SRT in both weak and strong scattering regimes.

$V = \text{CONCLUSION AND DISCUSSION}$

In conclusion, we have investigated the DP spin relaxation for the quasiparticle with a novel superconducting-velocity–tunable state in GaAs (100) QWs in proximity to an s-wave superconductor, by the KSBEs derived in the quasiparticle approximation. In the superconducting QW, the superconducting velocity induced from the superconducting phase is shown to cause the tilt of the quasiparticle energy spectrum. It is found that when the quasiparticle energy spectrum is tilted to be smaller than the chemical potential, a blocking region corresponding to the negative excitation energy appears, which is in the crescent shape. The existence of the blocking region can significantly influence the Cooper pairings, quasiparticle density and momentum current in QWs.

Specifically, the center-of-mass momentum $q$ is carried by the Cooper pairs, with the anomalous correlations only existing between the states with momentum $k+q/2$ and $-k+q/2$. Moreover, the Cooper pairings around the electron Fermi surface are efficiently suppressed. Furthermore, the quasiparticle density increases with the increase of the superconducting velocity. Particularly, the degenerate regime can be realized and the Fermi surface around the blocking region for the quasiparticles appears. The quasiparticle Fermi surface is constituted by the electron- and hole-like Fermi arcs. Finally, it is revealed that when the blocking region appears, the momentum current contributed by the quasiparticles flows in the opposite direction to the one carried by the Cooper pairs. Thus, in the superconducting velocity dependence of the momentum current, a peak arises due to the competition of the Cooper pairs and quasiparticles in the blocking region, whose appearance corresponds to the emergence of the blocking region.

We then study the DP spin relaxation for the quasiparticles in the superconducting QWs by the KSBEs. The KSBEs for the quasiparticle are set up based on the quasiparticle approximation, in which the SOC and quasiparticle-impurity scattering are explicitly considered. By using the KSBEs, the SRTs without and with the supercurrent are calculated. Rich physics is revealed. Without the supercurrent, we address that the branch-mixing scattering due to the impurity is forbidden, indicating that the electron- and hole-like branches are independent and hence only the intra-branch spin relaxation channel exists. In this situation, when $|\Delta|$ tends to zero, the SRT recovers to the normal one. Whereas with finite order parameter, we find that compared to the normal state, both the SOC and quasiparticle-impurity scattering are efficiently suppressed due to the same coherence factor $|\epsilon_k|/\Delta_k$. This leads to the enhancement of the SRT in both weak and strong scattering regimes.
with the boundary between the weak and strong scattering regimes unchanged.

When the supercurrent is turned on, the Fermi arc has intriguing effect on the DP spin relaxation, which exhibits very different physics depending on the magnitude of the order parameter. Specifically, when the order parameter is extremely small (e.g., $|\Delta| = 0.01$ meV), the branch-mixing scattering is still forbidden because the coherence factor ($\approx \epsilon_k/|\epsilon_k| + \epsilon_k/|\epsilon_k|$) tends to be zero in the quasiparticle-impurity scattering, indicating that the electron- and hole-like Fermi arcs are independent. Anomalous features are revealed for the quasiparticle spin relaxation at the Fermi arc in the strong scattering regime. Specifically, on one hand, the spin oscillations can be induced by the superconducting velocity; on the other hand, the SRT becomes insensitive to the momentum scattering. The latter feature is in contrast to the motional narrowing feature in the conventional DP relaxation in which the spin relaxation is suppressed by the momentum scattering.

With the finite order parameter ($|\Delta| \gtrsim 0.1$ meV), the situation becomes different. It is revealed that the tilt of the energy spectrum can trigger the branch-mixing scattering. In this situation, there exist not only the intra-branch spin relaxation channel, but also the inter-branch one. Furthermore, we reveal the role of the intra- and inter-branch spin relaxation channels on the spin relaxation in both the weak and strong scattering regimes. Specifically, in the weak scattering regime, the intra-branch spin relaxation channel is dominant; whereas in the strong scattering regime, the inter-branch channel becomes dominant when the blocking region appears. Moreover, it is found that in contrast to the situation with an extremely small order parameter, in the strong scattering regime, no spin oscillation occurs and the spin relaxation is suppressed by the momentum scattering.

Up till now, what predicted in this investigation has not yet been experimentally reported and we expect that our work will bring experimental attention. For the novel superconducting-velocity-tunable quasiparticle state in the QWs, the suppressed Cooper pairings, large quasiparticle density and non-monotonically tunable momentum current can be directly measured, which reflects the information of the tilted quasiparticle energy spectrum and the emergence of the blocking region. For the quasiparticle spin relaxation, when the order parameter is extremely small as reported in Ref. 38 ($|\Delta| = 46$ $\mu$eV), in the presence of the supercurrent, the spin oscillations and the insensitiveness of the SRT on the impurity density can provide the evidence for the existence of the Fermi arcs; when the order parameter is finite, in the strong scattering regime, the absence of the spin oscillations and the suppression of the SRT by the relatively large superconducting velocity (larger than the critical velocity) show the effect of the branch-mixing scattering on the quasiparticle spin relaxation.

Finally, we point out that the existence of the Fermi arcs can be markedly influenced by the dynamics of the quasiparticle condensation. It is important that the condensation rate is slower than the spin relaxation one. However, up till now, the details of the condensation process are not clear in superconductors, not to mention in the system proximity to a superconductor. Therefore, the study on the spin dynamics and the existence of the Fermi arc can even shed light on the condensation process.

**Appendix A: SPIN OSCILLATIONS INDUCED BY SUPERCONDUCTING VELOCITY**

In this appendix, we show the spin oscillations induced by the superconducting velocity in the strong scattering regime with extremely small order parameter. It has been addressed in Sec. IV B 2 that the angular-average of the effective magnetic field in one Fermi arc is not zero, which acts as an effective Zeeman field. Accordingly, even in the strong scattering regime, this effective Zeeman field can lead to the spin oscillations.

The impurity density is $n = 1$ (with the supercurrent $v_s = 0.1k_F/m^*$), the spin polarization oscillates in the temporal evolution. Whereas with a finite order parameter $|\Delta| = 0.5$ meV, it is shown by the red solid curve that when the order parameter is extremely small ($|\Delta| = 0.01$ meV), in the strong scattering regime ($n_e/n_i = 1$) with the supercurrent ($v_s = 0.1k_F/m^*$), the spin polarization oscillates in the temporal evolution. Whereas with a finite order parameter $|\Delta| = 0.01$ meV, no b-m oscillation occurs.

![FIG. 9: (Color online) Temporal evolution of the spin polarization](image-url)
quasi-electron can feel the SOC around the Fermi surface, whose angular-average is exactly zero. By arbitrarily switching off the branch-mixing scattering, the spin oscillations of the spin polarization occur, shown by the blue dashed curve.

The scattering term due to the interaction between quasi-electrons is derived to be

\[
\partial_t \rho_k^{\text{sc}} \mid_{\omega} = -\pi \sum_{k',k''} |V_{k-k'}|^2 |I_{k,k-k'+k''}|^2 |\rho_{k''}^{\text{sc}}|^2 \\
\times \delta(E_{k-k'+k''} - E_k + E_{k'} - E_{k''}) \left\{ (1 - \rho_k^{\text{sc}}) \rho_{k'}^{\text{sc}} - \rho_{k-k'+k''}^{\text{sc}} (1 - \rho_k^{\text{sc}}) \right\} \\
\times \text{Tr} \left[ (1 - \rho_k^{\text{sc}}) \rho_{k'}^{\text{sc}} - \rho_{k-k'+k''}^{\text{sc}} (1 - \rho_k^{\text{sc}}) \right] \right] \right\} \\
+ \text{H.c.,}
\]

with \(\rho_k^{\text{sc}} = \frac{1+i}{2} \rho_k^+\) being the density matrix for the quasi-electron. Here, \(I_{k,k'} = u_{k} u_{k'} - u_k u_{k'}^+\) is the coherence factor. From the scattering term, one sees that at low temperature, the quasiparticle-quasiparticle scattering is efficiently suppressed due to the coherence factor, which is proportional to \((\xi_0/\delta_k)^4\) approximately.
