Quantum non-demolition (QND) measurement of collective variables by off-resonant optical probing has the ability to create entanglement and squeezing in atomic ensembles. Until now, this technique has been applied to real or effective spin one-half systems. We show theoretically that the build-up of Raman coherence prevents the naive application of this technique to larger spin atoms, but that dynamical decoupling can be used to recover the ideal QND behavior. We experimentally demonstrate dynamical decoupling by using a two-polarization probing technique. The decoupled QND measurement achieves a sensitivity 5.7(6) dB better than the spin projection noise.

Quantum non-demolition measurement plays a central role in quantum networking and quantum metrology for its ability to simultaneously detect and generate non-classical quantum states. The original proposal by Braginsky [1] in the context of gravitational wave detection has been generalized to the optical [2, 3], atomic [4] and nano-mechanical [5] domains. In the atomic domain, QND by dispersive optical probing of spins or pseudo-spins has been demonstrated using ensembles of cold atoms on a clock transition [6, 7], and with polarization variables [8, 9], but thus far only with real or effective spin-1/2 systems.

Quantum measurement of larger spin systems offers a metrological advantage, e.g., in magnetometry [10], and may be essential for the detection of different quantum phases of degenerate atomic gases that intrinsically rely on large-spin systems [11–13]. Dispersive interactions with large-spin atoms are complicated by the presence of non-QND-type terms in the effective Hamiltonian describing the interaction [14–16]. As we show, and contrary to what has often been assumed [11–13, 17], these terms spoil the QND performance, even in the large-detuning limit. The non-QND terms introduce noise into the measured variable, or equivalently decoherence into the atomic state. The problem is serious for both large and small ensembles, so that naive application of dispersive probing fails for several of the above-cited proposals.

We approach this problem using the methods of dynamical decoupling [18–20], which allow us to effectively cancel the non-QND terms in the Hamiltonian while retaining the QND term. To our knowledge, this is the first application of this method to quantum non-demolition measurements. Dynamical decoupling has been extensively applied in magnetic resonance [21, 22], used to suppress collisional decoherence in a thermal vapor [23], to extend coherence times in solids [24], in Rydberg atoms [25], and with photon polarization [26]. Other approaches include application of a static perturbation [27, 28].

We consider an ensemble of spin-$f$ atoms interacting with a pulse of near-resonant polarized light. As described in references [14–16], the light and atoms interact by the effective Hamiltonian $\hat{H}_{\text{eff}}$,

$$\tau \hat{H}_{\text{eff}} = G_1 \hat{S}_x \hat{J}_x + G_2 (\hat{S}_x \hat{J}_x + \hat{S}_y \hat{J}_y),$$

(1)

where $\tau$ is the duration of the pulse and $G_{1,2}$ are coupling constants that depend on the atomic absorption cross section, the beam geometry, the detuning from resonance $\Delta$, and the hyperfine structure of the atom [29]. The atomic variables $\hat{J}$ (described below) are collective spin and alignment operators. The light is described by the Stokes operators $\hat{S}$ defined as $\hat{S}_i \equiv \frac{1}{2}(\hat{a}_i^\dagger, \hat{a}_i^{\dagger} \sigma_i(\hat{a}_+ + \hat{a}_-)^T$, where the $\sigma_i$ are the Pauli matrices and $\hat{a}_\pm$ are annihilation operators for the temporal mode of the pulse and circular plus/minus polarization. Bold subscripts, e.g., $\mathbf{x}$, are used to label non-spatial directions for atomic and light variables. The $G_1$ term describes a QND interaction, while the $G_2$ describes a more complicated coupling. In the dispersive, i.e. far-detuned, regime, $G_1$ and $G_2$ scale as $\Delta^{-1}$ and $\Delta^{-2}$, respectively. It has sometimes been assumed that the $G_2$ terms can be neglected for sufficiently large $\Delta$, leaving an approximate QND interaction. As we show below, this scaling argument fails, and the $G_2$ terms remain important. We note an important symmetry: $\hat{H}_{\text{eff}}$ commutes with $\hat{S}_z + \hat{J}_z$, and is thus invariant under simultaneous rotation of $\hat{J}$ and $\hat{S}$ about the $z$ axis.

The atomic collective variables are $\hat{J}_k \equiv \sum_{i=1}^{N_\lambda} \hat{j}^{(i)}_k$ where the superscript indicates the $i$-th atom and $\hat{j}_k \equiv (f^2 - f_0^2)/2, \hat{j}_y \equiv (f_x f_y + f_y f_x)/2, \hat{j}_x \equiv f_z/2$ and $\hat{j}_{[x,y]} \equiv -i[\hat{j}_x, \hat{j}_y] = f_z (f^2 - f_0^2 - 1/2)$. These obey commutation relations $[\hat{j}_x, \hat{j}_x] = i \hat{j}_y, [\hat{j}_y, \hat{j}_x] = i \hat{j}_x, [\hat{j}_x, \hat{j}_y] = i \hat{j}_{[x,y]}$. For $f = 1/2$, $\hat{j}_x, \hat{j}_y$ and $\hat{j}_{[x,y]}$ vanish identically while for $f = 1$, $\hat{j}_{[x,y]} = \hat{j}_z$ so that $\hat{j}_x, \hat{j}_y$, and $\hat{j}_z$ describe a pseudo-spin $\mathbf{j}$.

In the QND scenario, an initial coherent polarization state with ($\hat{S}$) = ($N_x/2, 0, 0$) is passed through the ensemble and experiences a rotation due to the $G_1$ term such that the component $\hat{S}_y$ (the ‘meter’ variable) indicates the value of $J_y$ (the ‘system’ variable). We assume that $J_x = N_A/2$. For a weak pulse, i.e., for $(\hat{S})$ sufficiently small, we have the following linear input-output relations $A^{(\text{out})} = A^{(\text{in})} - i\tau [A^{(\text{in})}, H_{\text{eff}}]$. Of specific interest are

$$j_x^{(\text{out})} = j_x^{(\text{in})} + G_2 S_x j_y^{(\text{in})} - G_2 S_y j_x^{(\text{in})}$$

$$j_y^{(\text{out})} = j_y^{(\text{in})} - G_1 S_x j_y^{(\text{in})} - G_2 S_y j_{x,y}^{(\text{in})}$$

$$\tilde{\kappa}_y^{(\text{out})} = \tilde{\kappa}_y^{(\text{in})} + G_1 S_x \tilde{\kappa}_y^{(\text{in})} - G_2 S_y \tilde{\kappa}_{x,y}^{(\text{in})}$$

which describe the change in the system variable, its conjugate, and the meter variable. In the case of $f = 1/2$, the $G_2$ terms vanish identically and we have a pure QND measurement: information about $J_y$ enters $\hat{S}_y$ and there is a back-action on $J_y$, but not on $J_x$. The input noise $\text{var}(\hat{S}_y^{(\text{in})}) = S_y/2$ limits the performance of the measurement, and corresponds to a spin sensitivity of $\delta J_y^2 = (2G_2^2 S_x)^{-1}$. For comparison, the projection noise of an x-polarized spin state is $\text{var}(\hat{J}_x) = J_x/2$, so that projection noise sensitivity is achieved for $\hat{S}_x = (G_2^2 J_y^2)^{-1} \equiv \text{SNR}$. This ideal QND regime does not occur naturally except for $f = 1/2$. In the interesting regime $\hat{S}_x \approx \text{SNR}$, we find that $G_2 S_x J_y \approx J_y (G_2 / G_1^2) / J_x$ is independent of $\Delta$, and cannot be neglected based on detuning. To get an order of magnitude, we note that for large detuning, $G_1 \approx \sigma_0 \Gamma / 4A\Delta$, $G_2 \approx G_1 \Delta_{\text{HFS}} / \Delta$ where $\sigma_0$ is the on-resonance scattering cross-section, $\Lambda$ is the effective area of the beam, and $\Gamma$ and $\Delta_{\text{HFS}}$ are the natural linewidth and hyperfine splitting, respectively, of the excited states. In terms of the on-resonance optical depth $d_0 \equiv \sigma_0 N_A / \Lambda$, we find $G_2 / G_1 J_x \approx 8\Delta_{\text{HFS}} / d_0 \Gamma$. In a typical experiment with rubidium on the D$_2$ line, $\Delta_{\text{HFS}} / \Gamma \approx 30$ and $d_0 \sim 50$ [29], so the contribution of this term is important.

In contrast, the last term in Eq. (3) and (4), respectively, contribute variances $\langle G_2^2 S_x^2 J_y^2 / \Delta^2 \rangle$ and $\langle G_2^2 S_x^2 J_y^2 / \Delta^2 \rangle$ which scale as $\Delta^{-2}$. We will henceforth drop these terms.

The system variable $J_y$ is coupled to a degree of freedom, $\tilde{J}_y$, which is neither system nor meter in the QND measurement. This coupling introduces noise into the system variable, and decoherence into the state of the ensemble. To measure the decoherence associated with this coupling $G_2 S_x J_y$, we adopt the strategy of “bang-bang” dynamical decoupling [18-20]. In this method, a unitary $\hat{U}_d$ and its inverse $\hat{U}_d^\dagger$ are alternately and periodically applied to the system $p$ times during the evolution, so that the total evolution is $[U_d^p U_H (t/2p) U_d U_H (t/2p)]^p$ where $U_H(t)$ describes unitary evolution under $H$ for a time $t$. With this evolution, those system variables that are unchanged by $\hat{U}_d$ continue to evolve under $H$, while others are rapidly switched from one value to another, preventing coherent evolution. For large $p$, the system evolves under a modified Hamiltonian $\hat{H}' = \hat{P} \hat{H}$, where $\hat{P}$ projects onto the commutant (i.e., the set of operators which commute with) of $(\hat{U}_b, \hat{U}_b^\dagger)$ [20].

To eliminate $G_2 S_x J_y + S_y J_y$, while keeping $G_1 S_x J_y$, we choose a $\hat{U}_d$ which commutes with $J_y$, but not with $J_x$ or $J_y$, namely a π rotation about $J_z$. $\hat{U}_b = \exp[i \tau J_z]$. This leaves $J_y$ unchanged, but inverts $J_x$ and $J_y$. By the symmetry of $H_{\text{eff}}$, this is equivalent to inverting $\hat{S}_x$ and $\hat{S}_y$, which suggests a practical implementation: probe with pulses of alternating $\hat{S}_x$, and define a ‘meter’ variable taking into account the inversion of $\hat{S}_y$.

We consider sequential interaction of the ensemble with a pair of pulses, with $\hat{S}_x^{(1)} = -\hat{S}_x^{(2)} = N_L / 4p$. We define also the new ‘meter’ variable $\hat{S}_y^{(\text{diff})} \equiv \hat{S}_y^{(1)} - \hat{S}_y^{(2)}$. We describe the atomic variables before, between, and after the two pulses with superscripts (in), (mid), (out), respectively. We apply Equations (2−4) to find:

$$\hat{j}_x^{(\text{mid})} = j_x^{(\text{in})} + G_2 S_x \tilde{\kappa}_y^{(\text{in})} + j_y^{(\text{in})}$$

$$\hat{j}_y^{(\text{mid})} = j_y^{(\text{in})} - G_1 S_x \tilde{\kappa}_y^{(\text{in})} - j_y^{(\text{in})} - G_2 S_y \tilde{\kappa}_{x,y}^{(\text{in})}$$

$$\tilde{\kappa}_y^{(\text{mid})} = S_y^{(\text{in})} + G_1 S_x \tilde{\kappa}^{(1)}_y$$

and

$$\hat{j}_x^{(\text{out})} = j_x^{(\text{in})} + G_2 S_x \tilde{\kappa}_y^{(\text{in})} + j_y^{(\text{in})}$$

$$\tilde{\kappa}_y^{(\text{diff}, \text{out})} = \tilde{\kappa}_y^{(\text{diff}, \text{in})} + G_1 S_x \tilde{\kappa}^{(1)}_y$$

plus terms in $G_1 G_2 S_x S_z J_x$, $G_2^2 S_x^2 \tilde{\kappa}_{x,y}$ and $G_1 G_2^2 S_x^2 J_z$ which become negligible in the limit of large $p$. The ideal QND form is recovered by the dynamical decoupling.

The presence of the $G_2$ term can be detected by noise scaling properties. While in the ideal QND of Equations (8),(9) the variance of the system variable is $\propto J_y$ giving a variance for the meter variable linear in $J_x$, for the imperfect QND of Equations (2) to (4) this is not the case: from Equation (6), we see that $\tilde{J}_y$ acquires a back-action variance $\propto J_y^2$, which then is fed into the system variable by the $G_2$ term. This additional $J_y^2$ noise is also reflected in the meter variable, and provides a measurable indication of $G_2$.

We use the two-polarization decoupling technique to perform QND measurement on an ensemble of $\sim 10^6$ laser cooled $^{87}$Rb atoms in the $F = 1$ ground state. In the atomic ensemble system, described in detail in reference [29], μs pulses interact with an elongated atomic cloud and are detected by a shot-noise-limited polarimeter. The experiment achieves projection noise limited sensitivity, as calibrated against a thermal spin state [9].

The experimental sequence is shown schematically in Fig. 1. In each measurement cycle the atom number $N_A$ is first measured by a dispersive atom-number measurement (DANM) [9]. A $J_x$-polarized coherent spin
The state (CSS) is then prepared and probed with pulses of alternating polarization to find the QND signal \( \hat{S}_y \equiv \sum_i \hat{s}_{y,i} \), immediately after, \( \langle \hat{J}_x \rangle \) is measured to quantify depolarization of the sample and any atoms having made transitions to the \( F = 2 \) manifold are removed from the trap, reducing \( N_A \) for the next cycle and allowing a range of \( N_A \) to be probed on a single loading.

To measure \( \hat{J}_x \), we send ten circularly-polarized probe pulses, i.e., with \( \langle \hat{S}_y \rangle = N_L/2 \), tuned 190 MHz to the red of the transition \( F = 1 \rightarrow F' = 1 \), while also applying repumping on the \( F = 2 \rightarrow F' = 2 \) transition and a weak magnetic field along \( x \) to prevent spin precession. The atoms arrive to this dark state after scattering fewer than two photons on average. To measure \( \langle \hat{J}_x \rangle \), we send ten circularly-polarized probe pulses, i.e., with \( \langle \hat{S}_y \rangle = N_L/2 \), tuned 190 MHz to the red of the transition \( F = 1 \rightarrow F' = 0 \). Each pulse, of 1 \( \mu \)s duration, contains \( 2.6 \times 10^6 \) photons and produces a signal \( \langle \hat{S}_y \rangle \propto G_2 \langle \hat{S}_x \rangle \langle \hat{J}_x \rangle \). The coherent state for the QND measurement is prepared in the same way, but in zero magnetic field.

To measure \( \hat{J}_x \), i.e., one half the population difference between \( |\uparrow\rangle \) and \( |\downarrow\rangle \), we send probe pulses of either vertical \( s_y = n_L/2 \) or horizontal \( s_y = -n_L/2 \) polarization through atomic sample and record their polarization rotation as \( \hat{s}_{y,i}^{(\text{out})} \). The number of individual probe pulses is \( 2p \) and the total number of probe photons \( N_L = 2pn_L \).

In Fig. 2 we plot the measured noise versus atom number, which confirms the linear scaling characteristic of the QND measurement. The black squares indicate the variance \( \text{var}(\hat{S}_y) \) normalized to the optical polarization noise, measured in the absence of atoms. Independent measurements confirm the polarimetry is shot-noise limited in this regime. The black solid line is the expected projection noise scaling \( 4\text{var}(\hat{S}_y)/N_L = 1+G_2^2N_L\text{var}(\hat{J}_x) \), calculated from the independently measured interaction strength \( G_1 \) and number of probe photons \( N_L = 8 \times 10^5 \).

The QND measurement achieves projection-noise limited sensitivity, i.e., the measurement noise is \( 5.7(6) \) dB below the projection noise.

Also shown are results of covariance matrix calculations, following the techniques of reference [30], including loss and photon scattering. The scenarios considered include the naive QND measurement, i.e., with a single polarization, and the “bang-bang” or two-polarization
QND measurement, with $p = 1, 2, 5$. These show a rapid decrease in the quadratic component with increasing $p$. This confirms the removal of $G_2$ due to the dynamical decoupling. Also included in these simulations is the term $J_y$ which introduces noise into $J_z$ proportional to $G_2^2 \text{var}(J_y) \langle J_x \rangle^2$. For our experimental parameters this term leads to an increase of $\text{var}(J_y)$ of less than 2% and as noted above could be reduced with increased de-tuning.

The dynamical decoupling also suppresses technical noise which would otherwise enter into $J_y$ through the interaction $G_2 (\hat{S}_x \hat{J}_x + \hat{S}_y \hat{J}_y)$. An imperfect preparation of the atomic and and/or light state, e.g., $\langle J_y \rangle \neq 0$ or $\langle \hat{S}_y \rangle \neq 0$, would otherwise be transferred into $J_y$.

Using dynamical decoupling techniques, we have demonstrated optical quantum non-demolition measurement of a large-spin system. We first identify an often-overlooked impediment to this goal: the tensorial polarizability causes decoherence of the measured variable, and prevents (naive) QND measurement of small ensembles. We then identify an appropriate dynamical decoupling strategy to cancel the tensorial components of the effective Hamiltonian, and implement the strategy with an ensemble of $\sim 10^6$ cold $^{87}$Rb atoms and two-polarization probing. The dynamically-decoupled QND measurement achieves a sensitivity $5.7(6)$ dB better than the projection noise level. The technique will enable the use of large-spin ensembles in quantum metrology and quantum networking, and permit the QND measurement of exotic phases of large-spin condensed atomic gases.

We gratefully acknowledge fruitful discussions with Ivan H. Deutsch and Robert Sewell. This work was funded by the Spanish Ministry of Science and Innovation under the ILUMA project (Ref. FIS2008-01051) and the Consolider-Ingenio 2010 Project “QOIT.”
