Introduction

Gasotransmitters are a group of ubiquitous small gaseous signalling molecules, which mainly consist of nitric oxide (NO), carbon monoxide (CO) and hydrogen sulphide (H₂S).¹ Their lipophilic nature allows them to freely permeate through the biological membranes and to play an essential role in the regulation of cellular processes.¹ ² Indeed, dysregulation of gasotransmitter system is associated with numerous diseases ranging from neurological disorders to musculoskeletal abnormalities.³–⁵ Recently, encouraging results have further indicated a regulatory role for gasotransmitters in immune cells.⁶ In particular, macrophage, as the patrolling sentinel in the immune system, is extensively regulated by these gaseous mediators.⁶

Summary

Hydrogen sulphide (H₂S) is the latest identified small gaseous mediator enabled by its lipophilic nature to freely permeate the biological membranes. Initially, H₂S was recognized by its roles in neuronal activity and vascular relaxation, which makes it an important molecule involved in paracrine signalling pathways. Recently, the immune regulatory function of gasotransmitters, H₂S in particular, is increasingly being appreciated. Endogenous H₂S level has been linked to macrophage activation, polarization and inflammasome formation. Mechanistically, H₂S-induced protein S-sulphydration suppresses several inflammatory pathways including NF-kB and JNK signalling. Moreover, H₂S serves as a potent cellular redox regulator to modulate epigenetic alterations and to promote mitochondrial biogenesis in macrophages. Here in this review, we intend to summarize the recent advancements of H₂S studies in macrophages, and to discuss with focus on the therapeutic potential of H₂S donors by targeting macrophages. The feasibility of H₂S signalling component as a macrophage biomarker under disease conditions would be also discussed.

Keywords: epigenetics; H₂S; macrophage function; redox regulation; S-sulphydration.
Upon activation, the classically activated (M1) macrophages upregulate the expression of inducible nitric oxide synthase (iNOS), and catalyse the transformation of L-arginine to NO. Elevated NO along with the production of reactive nitrogen species is indispensable for the optimal antimicrobial activity and the secretion of inflammatory cytokines such as IL-6, TNF-α and interferons. On the other hand, the alternatively activated (M2) macrophages highly express the hallmark enzyme Arginase1 (Arg1), which outcompetes the activity of iNOS on L-arginine availability and reduces the NO production. Therefore, the fluctuation of NO metabolism serves as a key molecular switch for control of macrophage function to dynamically regulate the initiation or resolution of an inflammatory response. In contrast to NO, CO, a haem metabolism product produced by the haem oxygenase 1-3 (HO 1-3), attenuates macrophage activation, and therefore, HO-1 overexpression in myeloid lineages favours M2 programme in macrophages and implies better outcome in liver transplant patients. Consistently, HO-1 deficiency leads to increased M1 macrophages along with enhanced inflammatory infiltration following ischaemia–reperfusion injury. Similarly, CO suppresses lipopolysaccharide (LPS)-induced macrophage activation and induces the secretion of IL-10, which involves its effect on the activation of mitogen-activated protein kinase 3 (MKK3). H2S, the latest identified gasotransmitter, was first recognized as a smelly and environmental toxic gas. Past two decades of studies revealed that H2S can be generated endogenously and work as an autocrine signalling molecule. In mammals, three enzymes including cystathionine γ-lyase (CSE), cystathionine β-synthase (CBS) and the 3-mercaptopyruvate sulphur transferase (3-MST) are responsible for H2S generation. Specifically, CSE and CBS catalyse de-sulphydration of cysteine to generate H2S, while MST induces H2S production by regulating the enzymatic activity of cysteine aminotransferase. The essential role of H2S signalling in T-cell biology has been well addressed, in which ablation of CBS and CSE leads to impaired T-cell activation and proliferation. Mice deficient in CBS also manifest reduced regulatory T cells along with massive inflammatory infiltration, which could be reversed by H2S donor supplementation.

Interestingly, unlike its effect on T cells, in macrophages, H2S signalling is clearly anti-inflammatory in a variety of interesting ways. It seems that H2S actively impact macrophage on its activation, polarization and inflammasome formation through distinct mechanistic pathways. Particularly, macrophages likely also set the threshold for the activation of H2S signalling under various stimuli. Herein, we aim to summarize the regulatory mechanisms underlying H2S signalling and discuss with focus for the impact of H2S signalling on the regulation of macrophage functionality. We also discuss the potential that the cellular H2S content and the key H2S metabolic enzymes serve as ideal biomarkers to indicate distinct macrophage activation status.

The regulatory mechanisms underlying H2S signalling

H2S signalling plays a critical regulatory role in diverse immune responses, which involves H2S-induced protein S-sulphydration, cellular redox homeostasis and epigenetic chromatin remodelling (Fig. 1). In this section, we briefly summarize the above regulatory mechanisms underlying H2S signalling.

Protein S-sulphydration

H2S-induced protein S-sulphydration is a novel post-translational modification occurring on specific cysteine (Cys) residues of target proteins, by which it regulates the biological activity of targeted proteins. It is noteworthy that S-sulphydration of key enzymes, receptors and transcriptional factors contributes a major part to H2S signalling and its regulatory function. Kir6.1, a subunit of ATP-sensitive potassium channels (KATP), is S-sulphydrated at Cys43, which promotes KATP channel activity and improves vasodilation. Other ion channels such as voltage-activated calcium channels, and transient receptor potential channel proteins TRPV6 and TRPV4, were also suggested to be S-sulphydrated, thereby regulating calcium flux. Together, these events perfectly explain the effect of endogenous H2S and exogenous H2S donors on vascular relaxation.

Metabolic reprogramming and stress responses including oxidative stress and endoplasmic reticulum (ER) stress are critical regulators in immune cells and their fate decision. Other than the well-known role in cardiovascular system, H2S-mediated protein S-sulphydration also engages in the metabolic processes and cellular stress responses. S-sulphydration of peroxisome proliferator-activated receptor-γ (PPARγ) at Cys139 enhances its DNA binding activity and the subsequent expression of adipogenic genes, thus increasing glucose uptake and lipid metabolism. Additionally, H2S promotes the activities of PPARγ coactivator-related protein (PPRC), alpha subunit of ATP synthase (ATP5A1) and interferon regulatory factor 1 via S-sulphydration, by which it stimulates mitochondrial biogenesis and protects against mitochondrial dysfunction. P66Shc is an upstream activator of mitochondrial redox signalling, and studies suggested that H2S protects neuronal cells against stress-induced senescence by inducing its S-sulphydration at Cys59 residue. H2S also induces Keap1 S-sulphydration (Cys151, Cys226 and Cys613) to promote the dissociation of Keap1-Nrf2 complex, thereby releasing Nrf2 to transcribe the expression of antioxidant genes. Similarly, PTP-1B is a
protein tyrosine phosphatase related to the deactivation of protein kinase RNA-like ER kinase (PERK), while H$_2$S mediates PTP-1B S-sulphydration at Cys215 to inhibit its enzymatic activity, thereby activating PERK pathway to alleviate ER stress.\textsuperscript{31}

It is worthy of note that some immune regulatory molecules are the direct targets for H$_2$S-induced S-sulphydration. For example, S-sulphydration of nuclear transcription factor Y subunit beta (NFYB) at Cys105 increases the transcription of the ten-eleven translocation (Tet) genes.\textsuperscript{32} Tet1 and Tet2 in turn bind to the regulatory regions within the Foxp3 gene to maintain the hypomethylation status of its promoter and the conserved non-coding sequence 2 (CNS2) region, thereby ensuring Foxp3 expression and the stability of Treg cell lineage.\textsuperscript{20} Similarly, S-sulphydration of the free thiol group Cys38 in p65 inhibits NF-$\kappa$B activity in macrophages.\textsuperscript{33} Moreover, S-sulphydration of c-Jun at Cys269 attenuates hydrogen peroxide (H$_2$O$_2$)-induced NLRP3 inflammasome activation and reduces IL-1$\beta$ production in macrophages.\textsuperscript{34}

**Cellular redox homeostasis**

Theoretically, most H$_2$S can dissolve in surface water and dissociate into HS$^-$ under normal circumstances (37\textdegree, pH = 7.4),\textsuperscript{35} and HS$^-$ in turn could serve as a powerful one-electron chemical reductant to scavenge ROS. In reality, however, the physiological concentration of H$_2$S is at the sub-micromolar level,\textsuperscript{36} which is too low for H$_2$S to act as a direct antioxidant. Nonetheless, low concentration of endogenous H$_2$S can exert potent antioxidant effects in alternative manners. Specifically, other than the aforementioned Keap1 S-sulphydration-mediated pathway, hypoxia-inducible factor 1$\alpha$ (HIF-1$\alpha$) also serves as another important molecule downstream of H$_2$S signalling.\textsuperscript{37} Studies in THP-1 cells, a human macrophage cell line, revealed that H$_2$S induces HIF-1$\alpha$ nuclear translocation to enhance the expression of glucose transporter GLUT1 along with the abrogation of its pro-inflammatory effect.\textsuperscript{37} Consistently, it was also found that H$_2$S could activate the antioxidant Nrf2/HO-1 pathway by stimulating the p38 mitogen-activated protein kinase (MAPK) activity.\textsuperscript{37} Therefore, H$_2$S has been found to attenuate LPS-induced acute lung injury by reducing oxidative and nitrative species,\textsuperscript{38} and H$_2$S administration improves glutathione (GSH) level along with alleviated lipid peroxidation and allergic lung inflammation.\textsuperscript{39} Collectively, as a negative regulator in cellular redox homeostasis, H$_2$S exhibits anti-inflammatory potency amid stress-related inflammatory disorders.

**Epigenetic chromatin remodelling**

Another critical mechanism underlying H$_2$S signalling is that H$_2$S also manifests a remarkable capacity to regulate epigenetic chromatin remodelling. Apart from the above-introduced NFYB-Tet pathway, which mediates DNA demethylation of the Foxp3 regulatory regions in Treg cells, H$_2$S exhibits high potency to remodel chromatin.
structure through regulation of histone modifications in macrophages.

The Jumonji domain-containing protein 3 (JMJD3) is a histone 3 Lys27 (H3K27) demethylase and plays a critical role in chromatin remodelling.40 There is evidence that LPS upregulates CSE expression in macrophages in a mouse model with septic shock, and enhanced CSE in turn inhibits JMJD3 expression to increase H3K27me3 levels, thereby attenuating LPS-mediated inflammatory response.41 Studies in macrophages further noted that H2S is capable of suppressing histone acetylation at the IL-6 and TNF-α promoter, by which it inhibits chromatin openness to repress the transcription of inflammatory cytokines following LPS stimulation.42 Although no direct evidence shows the existence of H2S-NFYB-Tet pathway in macrophage, Tet2 resolves macrophage inflammatory response by recruiting HDAC2 and deacetylating permissive histone markers in the IL-6 promoter, the mechanism of which is DNA methylation-independent and quite different from what happens in Treg cells.43 These results suggest that the CSE/H2S signalling could be vital to prevent uncontrolled macrophage inflammatory responses via epigenetic machineries.

Heretofore, the major mechanism underlying H2S signalling is likely attributed to the S-sulphydration of substrate proteins (Table 1). Moreover, the impact of H2S signalling on the regulation of redox homeostasis and chromatin remodelling seems independent of S-sulphydration, but additional studies would be necessary to fully address this issue. It should be also important to keep in mind that characterization of additional unidentified S-sulphydration proteins would help to completely clarify the regulatory mechanisms.

H2S signalling in maintaining the M1/M2 homeostasis in macrophages

As described earlier, macrophages display different functional phenotypes depending on their residing environmental milieu. For simplicity, they are classified into two distinct subtypes: one is classically activated (M1) macrophages, and the other is alternatively activated (M2) macrophages. LPS and IFN-γ induce the generation of M1 macrophages, which then augment the production of pro-inflammatory cytokines. In contrast, M2 macrophages are elicited by glucocorticoids or type II cytokines such as IL-4, IL-13 and IL-10. M2 macrophages are responsible for wound healing, tissue repair and the resolution of inflammation, thus generally regarded as an anti-inflammatory cell type.

Recent studies provided compelling evidence that H2S signalling is implicated in dictating macrophage polarizations. Initially, the endogenous H2S was found to attenuate LPS-induced oxidative stress and inflammatory damage by inhibiting NOX4-ROS signalling pathway in macrophages.44 GYY4137, a novel H2S-releasing molecule, was confirmed to inhibit rat endotoxic shock and mucosal wound through abrogating M1 programme in macrophages.45,46 Similarly, FW1256, another slow-releasing H2S donor, was further noted to exhibit anti-inflammatory properties by reducing the production of inflammatory mediators such as TNF-α, IL-6, PGE2, IL-1β, COX-2 and NO in macrophages.47 Subsequent mechanistic studies demonstrated that NaHS promotes macrophage M2 polarization by enhancing mitochondrial biogenesis and fatty acid oxidation (FAO).48 Similar results were also observed in the central nervous system, in which H2S exerts neuroprotection against hypoxia-induced neurotoxicity through induction of M2 programme in microglia cells by inhibiting iNOS, NF-xB, ERK and p38 MAPK signalling pathways.49 Therefore, H2S signalling serves as a critical regulatory mechanism to maintain the homeostatic M1/M2 balance in the setting of inflammatory resolution.

H2S signalling in macrophage activation and inflammasome formation

It was noted that LPS-stimulated macrophages and adipose tissue macrophages (ATMs) derived from diet-

Table 1. Potential S-sulphydration targets relevant to macrophage regulation

| Potential target | Modification site | Major cell types | Biological consequence | Reference |
|------------------|-------------------|------------------|------------------------|-----------|
| P65              | Cys38             | Macrophage       | Inhibiting NF-κB activity | 33        |
| c-Jun            | Cys269            | Macrophage       | Attenuating inflammasome activation and IL-1β production | 34        |
| Keap1            | Cys151, Cys8226, | Fibroblast       | Dissociation of Keap1-Nrf2 complex; antioxidative response | 30,31     |
|                  | Cys613            |                  |                        |           |

induced obese mice manifest lower intracellular concentration of H2S, suggesting that depletion of macrophage H2S content occurs during both acute (LPS-induced) and chronic (obesity) inflammatory conditions. Indeed, oxidized low-density lipoprotein (oxLDL) induces the CSE promoter to undergo DNA hypermethylation in macrophages, leading to attenuated CSE transcription and H2S production in favour of inflammatory responses, which involves the activation of JNK/NF-κB signalling. Similarly, homocysteine (Hcy) induces DNA hypermethylation in the CSE promoter in macrophages, through which it exaggerates inflammation by inhibiting CSE-H2S signalling (Fig. 2).

In line with above observations, a time-dependent change of H2S content in macrophages was found following activation. A decrease of H2S level in murine macrophages following 24 hr of LPS or IFN-γ stimulation was observed (early phase), but the H2S content was restored to normal level after 48 hr of stimulation (late phase), which was associated with the feedback regulation between CBS and CSE. It is worthy of note that H2S production was correlated with LPS-induced macrophage late-stage apoptosis, which could be blocked by the addition of H2S inhibitor. Therefore, it is possible that sustained LPS stimulation renders macrophages that undergo apoptosis through the production of H2S (Fig. 2).

Macrophages not only sense exogenous pathogen-associated molecular patterns (e.g. LPS) derived from microorganisms, but also respond to endogenous stimuli. The most commonly seen endogenous insults originate from harmful metabolites, such as excessive free fatty acids (FFAs) and oxLDL. Interestingly, these metabolites alone could lead to abnormal macrophage activation, while they could also serve as the second signals essential for inflammasome formation. Inflammasome is a complex of proteins found in macrophages that regulates the activation of caspase enzymes and induces the secretion of pro-inflammatory cytokines (e.g. IL-1β and IL-18). Importantly, recent studies demonstrated that both exogenous and endogenous H2S inhibit NLRP3 inflammasome activation and reduce inflammatory cytokine production in macrophages. In particular, upregulation of H2S content by treating the cells with NaHS reduces the expression level of inflammasome-associated proteins such as TXNIP, NLRP3, ASC and caspase-1 by inhibiting thioredoxin-interacting protein–NLRP3 (TXNIP-NLRP3) signalling pathway. Taken together, H2S signalling not only directly represses macrophage activation, but also inhibits inflammasome formation, thereby attenuating inflammatory responses.

Figure 2. H2S signalling regulates macrophage functionality for the initiation and resolution of an inflammatory response. Upon stimulation (e.g. LPS and oxLDL), H2S production is shut down at the early stage to facilitate pro-inflammatory cytokine secretion, while at the late stage, the H2S content becomes increased for induction of those mission-completed macrophages to undergo apoptosis. Alerted H2S signalling would lead to the development of immune or metabolic disorders. LPS, lipopolysaccharide; oxLDL, oxidized low-density lipoprotein.
The therapeutic potential for targeting H$_2$S signalling in macrophages

Macrophages are critical participants in the immune system, which are involved in innate immunity and also help to recruit other immune cells for adaptive immune responses. Macrophages can be found essentially in all tissues, and their dysfunction is linked to a variety of diseases. Dysregulation of macrophages is related to various diseases ranging from infection to metabolic disorders, wherein H$_2$S donors exhibit significant therapeutic potential.

It has been well recognized that enhanced H$_2$S signalling in macrophages abrogates the progression of septic shock, a severe inflammatory disorder caused by bacterial infection and now faces up with limited therapeutics in clinic. Microglia, a specialized macrophage in the nervous system, is involved in the pathogenesis of Alzheimer’s and Parkinson’s disease. Given the role of H$_2$S signalling in the resolution of neuronal inflammation, H$_2$S donors are proven to be effective in numerous neuronal disorders.

Similarly, as H$_2$S reduces FFAs and oxLDL-induced metabolic stress and inflammasome formation, H$_2$S donors could inhibit foam cell formation and attenuate the release of pro-inflammatory cytokines, thus leading to the amelioration of arterial atherosclerosis and other inflammasome-associated diseases such as DSS-induced colitis. MicroRNA-186 (miR-186) plays an important role in atherosclerotic diseases. Mechanistic study revealed that miR-186 directly binds to the 3’-UTR of CSE and destabilizes the mRNA transcripts. As a result of decreased CSE-H$_2$S axis, the human macrophages take up more lipids and become pro-inflammatory.

Exogenous administration of H$_2$S donor NaHS or GYY4137 decreases the inflammatory cytokine secretion, prohibits lipid accumulation in macrophages and down-tunes the expression of chemokine receptors (CX3CR1 in particular), thus demonstrating the effectiveness in atherosclerosis treatment. As aforementioned, intracellular concentration of H$_2$S was lower in ATMs of obese mice, and not surprisingly, exogenous supplementation of H$_2$S donors could curb the development of obesity and the subsequent metabolic syndromes.

Alternatively activated M2 macrophages substantially participate in inflammation resolution and tissue repair. Given the role of H$_2$S signalling played in M2 macrophages, it is not surprising that H$_2$S would play a pivotal role in myocardial infarction (MI) and wound healing. Studies showed that H$_2$S promotes macrophage migration towards the infarcted area at the early stage, then induces M2 polarization by enhancing mitochondrial biogenesis and FAO, the two steps of which cooperatively accelerates the post-MI recovery. During the wound healing process, the local H$_2$S content was found to significantly reduce amid injured tissue granulation. Replenishment of H$_2$S inhibits macrophage activation and improves wound healing in both oral mucosal wound model and diabetic wound model. In situ induction of M2 macrophages by employing the novel H$_2$S-releasing hydrogel greatly improves wound healing process, which displays a promising translational potential. Together, these results support that targeting H$_2$S signalling in macrophages could be a viable approach to fight against immune and metabolic disorders in clinical settings and to restore tissue homeostasis upon trauma.

Concluding remarks and perspectives

It would be important to note that the relationship between H$_2$S signalling and macrophage functionality is reciprocal and dynamic. H$_2$S actively modulates macrophage activation, polarization and inflammasome formation (Fig. 1), and macrophages in turn influence the intrinsic H$_2$S synthetic machinery following external stimuli. Specifically, upon LPS stimulation, H$_2$S production is shut down at the early stage to facilitate pro-inflammatory cytokine secretion, while at the late stage, the H$_2$S content becomes increased for induction of those mission-completed macrophages to undergo apoptosis. This complex feedback loop underpins the multifaceted function of macrophages, which reflects a fine control of macrophage-mediated immune response (Fig. 2).

Generally, H$_2$S induces S-sulphydration of key signalling molecules, such as p65 and c-Jun, to impact on NF-kB pathway and canonical NLRP3 inflammasome formation, while H$_2$S also regulates cellular redox homeostasis and chromatin remodelling to affect macrophage function. However, we cannot exclude the possibility that additional unrecognized S-sulhydrated proteins could be also engaged in H$_2$S signalling. As for the regulation of cellular redox homeostasis, it is intriguing that H$_2$S-induced S-sulphydration shares great similarity as GSH-mediated S-glutathionylation, and both of which even possess the same substrate, PTP1B. There is evidence that S-glutathionylation regulates redox homeostasis, and a typical example is MKP1, which has been verified to be a substrate for S-glutathionylation. It is therefore plausible that H$_2$S could either directly mediates MKP1 S-sulphydration to regulate macrophage redox homeostasis, or indirectly influences MKP1 S-glutathionylation by elevating GSH levels, which could perfectly explain the inhibitory effect of H$_2$S on MAPK signalling.

Macrophages demand distinct intracellular metabolic pathways depending on their functional state. The activation of M1 macrophages by LPS or IFN-γ is associated with higher glycolysis along with attenuated tri-carboxylic acid (TCA) cycle and mitochondrial oxidative phosphorylation (OXPHOS). In contrast, M2 macrophages require higher mitochondrial biogenesis, fatty acid uptake and...
Collectively, those discoveries support that H2S-mediated metabolic reprogramming finely controls the initiation and resolution of an inflammatory response. Therefore, a better understanding of the role for H2S signalling in macrophages would demonstrate great potential to develop therapies against either acute or chronic inflammatory responses in clinical settings of patients with immune or metabolic disorders. Indeed, some commonly prescribed drugs have already been indicated to affect endogenous H2S signalling pathway. For example, statins are able to modulate H2S metabolism⁷⁷,⁷⁸ in the cardiovascular system, while the well-known antidiabetic drug, metformin, could promote H2S production by elevating GSE⁷⁹. These discoveries prompt us to recrystallize the ‘new function of old drugs’ while pursuing for novel H2S regulating compounds in the future investigations.
