Abstract

**Background:** Several felids are endangered and threatened by the illegal wildlife trade. Establishing geographic origin of tissues of endangered species is thus crucial for wildlife crime investigations and effective conservation strategies. As shown in other species, stable isotope analysis of hydrogen and oxygen in hair ($\delta$D, $\delta^{18}$O) can be used as a tool for provenance determination. However, reliably predicting the spatial distribution of $\delta$D and $\delta^{18}$O requires confirmation from animal tissues of known origin and a detailed understanding of the isotopic routing of dietary nutrients into feld hair.

**Methodology/Findings:** We used coupled $\delta$D and $\delta^{18}$O measurements from the North American bobcat (Lynx rufus) and puma (Puma concolor) with precipitation-based assignment isoscapes to test the feasibility of isotopic geo-location of felidae. Hairs of feld and rabbit museum specimens from 75 sites across the United States and Canada were analyzed. Bobcat and puma lacked a significant correlation between H/O isotope ratios in hair and local waters, and also exhibited an isotopic decoupling of $\delta^{18}$O and $\delta$D. Conversely, strong $\delta$D and $\delta^{18}$O coupling was found for key prey, eastern cottontail rabbit (Sylvilagus floridanus; hair) and white-tailed deer (Odocoileus virginianus; collagen, bone phosphate).

**Conclusions/Significance:** Puma and bobcat hairs do not adhere to expected pattern of H and O isotopic variation predicted by precipitation isoscapes for North America. Thus, using bulk hair, felids cannot be placed on $\delta^{18}$O and $\delta$D isoscapes for use in forensic investigations. The effective application of isoscapes to trace the provenance of feline carnivores is likely compromised by major controls of their diet, physiology and metabolism on hair $\delta^{18}$O and $\delta$D related to body water budgets. Controlled feeding experiments, combined with single amino acid isotope analysis of diets and hair, are needed to reveal mechanisms and physiological traits explaining why feld hair does not follow isotopic patterns demonstrated in many other taxa.

Introduction

Many carnivore species are currently threatened and are the focus of intense conservation concern [1]. Feline carnivores are often subject to illegal wildlife trade, thus the ability to estimate the geographic provenance of illegal tissue samples would constitute important information in wildlife crime investigations [2]. Probabilistic provenance determination based on O and H isotopes has strong potential to be applied to animal tissues as an investigative tool in wildlife forensic science [3–6]. Validation of isotopic methods has relevance and practical application in various fields like wildlife forensics and conservation biology.

Measurements of the stable isotopes of hydrogen ($\delta$D) and oxygen ($\delta^{18}$O) of animal keratinous tissues have been used to track the geographic origin and migratory patterns in a wide variety of animals [e.g. 3,4,7–9]. To date, this approach is based on strong empirical correlations between $\delta$D values in animal tissues ($\delta$D$_t$) with the isotopic composition of the amount-weighted mean annual or mean-growing season precipitation ($\delta$D$_p$). The latter correlates inversely with latitude and elevation across the continents, especially in North America [10–12]. Few studies have coupled $\delta$D and $\delta^{18}$O measurements of the organic or inorganic fractions of animal tissues despite the strong covariance between these isotopes in environmental waters (hairs and nails: human [8,13–16]; CO$_2$, body water, hair and enamel: woodrat [17]; chitin: brine shrimp [18]; chitin: chironomids [19]; plasma, blood and feathers: birds [20,21]; fat, blood, muscle, hair and collagen: pig [22]; carbonate and phosphate tooth enamel, bone collagen, subcutaneous fat and hair: laboratory rat [23]). Strong correlations between $\delta$D$_p$ and $\delta$D$_t$ have been found for many species [4]. The hydrogen and oxygen isotopic composition of animal tissues (hair, feathers, teeth) is related to the isotopic composition of body water (e.g. [24–27]) and ultimately to that of ingested water. Influences on isotopic composition of body water ($\delta$D$_{bw}$, $\delta^{18}$O$_{bw}$) of animals include abiotic (climate, drinking water) and biotic (diet and physiology) factors [28–35]. The incorporation of H and O isotopes from the hydrosphere via diet and drinking water into animal tissues is a complex process and our
understanding of how these mechanisms affects the nature and variability of the empirically observed relationships is still poor (e.g. [13]). However, to reliably track the geographic origin of an animal requires a detailed understanding of the metabolic routing of dietary nutrients and mechanisms of H and O isotopic incorporation into animal tissues [36].

Hydrogen and oxygen in animal tissues can be derived from two potential sources: dietary nutrients and body water, whereas oxygen is also derived from inhaled air. The body-water pool, in turn, is derived from ingested drinking-water, food, and metabolic-water produced during the catabolism of food macromolecules [28,30,32,35,37–39]. The relative contributions of all these sources to protein synthesis (i.e. keratin and collagen) are likely to vary among animals [40–42]. Controlled experiments are key to understand and model the incorporation of H and O isotopes into proteinaceous tissues like keratins (hair and feathers), collagen, and chitin, and have so far been developed for only a small number of species like woodrat (Neotoma cinerea and Neotoma stephensi; [17]), rat (Rattus norvegicus; [23]), Japanese quail (Coturnix japonica; [24]), house sparrow (Passer domesticus; [21]), humans (Homo sapiens; [8,13–16,27], pig (Sus scrofa domestica; [22]), brine shrimp (Artemia franciscana; [18]) and chironomids (Chironomus dilutus; [19]). These studies revealed that keratin 18O and 18D reflect both biological (diet, physiology) and environmental signals (water, geographic movement, climate; [13]). Deviations from a strong coupling between 18D, and 18Dh, and 18O2H and 18O2H, have been shown (e.g. [13,43]) and may be linked to: 1) climatic factors like geographic movement, climate; [13]). Deviations from a strong biological (diet, physiology) and environmental signals (water, geographic movement, climate; [13]). Deviations from a strong biological (diet, physiology) and environmental signals (water, geographic movement, climate; [13]). Deviations from a strong biological (diet, physiology) and environmental signals (water, geographic movement, climate; [13])).

For H/O isotopic analyses, the latter representing the preferred prey species of the bobcat, were obtained from the Smithsonian National Museum of Natural History in Washington D.C. and the Utah Museum of Natural History, Utah. Published isotope data of bone-phosphate (18O3P) and bone collagen (18O3C) from white tailed deer (Odocoileus virginianus), constituting the major prey of the puma, were included for comparative analysis [56]. For each specimen, geographic location, sex and elevation was recorded (Table S1). All specimens studied originated from 75 different sites across the United States and Canada (Figure 1). Sample locations ranged in latitude from 25.0 to 49.2°N and longitude from 124.4 to 65.8°W, covering strong altitudinal (2 to 3400 m) and isotopic gradients (18O3H = −17.5% to −0.16%o; 18D3H = −192.7% to 0.6%o).

Stable isotope analysis

Sample preparation and H/O isotope analysis were conducted at Environment Canada. All keratin samples were physically cleaned of adhering debris and washed twice in a 2:1 mixture of chloroform and methanol to remove lipids from the keratin surface. After cleaning, all samples were air-dried for 24 h. Hair samples were then cut into 0.5 cm increments (H: 350–20 g) and weighed into pre-combusted silver foil (99.999% pure, 20 mg; O: 700±50 µg) and weighed into pre-combusted silver foil capsules for H and O isotope ratio analysis. For 18D, in order to account for exchangeable hydrogen in hair proteins, we used comparative equilibration with in-house keratin working standards, BVB (−100%), CPS (−147.7%), CHS (−187%), for which the 18D value of non-exchangeable H had been previously established [57]. For 18O, we used the IAEA benzoic acid standards IAEA 601 and 602, with assigned 18O values of +23.1%o and +71.4%o, respectively. For H/O isotopic analyses, samples and reference materials were separately pyrolyzed on a Hekatech HTO elemental analyser at 1530°C to H2 and CO for isotopic analysis on an Isoprime™ dual-inlet isotope-ratio mass spectrometer. The reference standards were used to normalize unknown samples to the Vienna Standard Mean Ocean Water.
Estimates of drinking water isotope compositions ($\delta^D$, $\delta^{18}O$) for bobcat and puma

The H and O isotopic composition of water ingested by both felid species indirectly from their prey were inferred from modeled isoscape values [58] as well as measured river water values across North America [59,60]. It was assumed that the place of death of each puma and bobcat reflected their lifetime habitat. For each locality the average $\delta^D$ and $\delta^{18}O$ values for precipitation were determined using the Online Isotopes in Precipitation Calculator (OIPC) version 2.2 (http://www.waterisotopes.org). The OIPC provided a model estimation of long-term annually or monthly averaged precipitation isotope ratios at specified locations through spatial modelling of a large database of precipitation isotopic data covering the time period 1960–2004 [10,58]. The $\delta^D$ and $\delta^{18}O$ data of the OIPC model were compared to those measured for local river waters [59,60]. In general, there was a good correlation between $\delta^D_{riv}$ and $\delta^{18}O_{riv}$ and $\delta^D_{p}$ and $\delta^{18}O_{p}$ for relatively small-to medium-sized drainage catchments (<150,000 km$^2$) [9]. As puma and bobcats have smaller home-range sizes (female bobcat: 21.7 km$^2$, [61,62]; female puma 175.8 km$^2$, [61]) local river water should reflect the average $\delta^D$ and $\delta^{18}O$ values of ingested prey-derived drinking water. Therefore we compared the hair $\delta^D_{h}$ and $\delta^{18}O_{h}$ data with the river water data.

Bobcat and puma hair isotope values were plotted against amount-weighted long-term annual, spring (three months mean of March, April, May) and summer (three months mean of June, July and August) precipitation $\delta^D_{p}$ and $\delta^{18}O_{p}$ values, because the formation and isotopic incorporation of cat hair is limited to a rather short time period. For instance hair growth
in domestic cats is not continuous [63], but rather includes an anagen phase of active growth and a telogen phase of rest [64]. The hair-growth phase takes 6–8 weeks and 70% percent of the hair follicles are in the anagen phase during the summer [65]. Isotopic signals from drinking water and prey consumed during the anagen phase of growth are most likely integrated into the growing hairs. For this reason we related the isotope values of hair $\delta D_h$ and $\delta^{18}O_h$ not only to annual average $\delta D_p$ and $\delta^{18}O_p$ values but also to seasonal spring and summer precipitation to test if a better relation with water isotope values of the likely main hair growing season was obtained (Table S2).

**Statistical analysis**

First, we analysed the H and O isotopic variation of puma and bobcat hairs among locations and their correlation with the large-scale patterns of isotopic variation in precipitation. We tested whether the correlations significantly changed when using the annual and summer modeled precipitation or local river water data (Table S2). We compared hair H and O isotope data of predators and respective prey species and tried to establish a calibration equation between river water and hair for a feline carnivore. Relationships between mean annual $\delta^{18}O_{riv}$, $\delta D_{riv}$ and $\delta^{18}O_{riv}$, $\delta D_{riv}$ of puma, bobcat and rabbit hairs were investigated using linear regressions (Figure 2 and 3). We also examined the relationship between $\delta^{18}O_h$ and $\delta D_h$ (Figure 4). The effects of species, age, sex, seasonal precipitation and relative humidity on hair isotope values were examined using a General Linear Model (GLM) (Table S2). Statistical tests were conducted using XLSTAT (V 7.5.2).

**Results**

All hair $\delta D_h$ and $\delta^{18}O_h$ values were plotted against mean annual $\delta D_{riv}$ and $\delta^{18}O_{riv}$ values because using either amount-weighted mean annual, summer (June, July and August) or spring (March, April and May) OIPC modeled precipitation values did not significantly change the results (Table S2). The $\delta^{18}O_h$ - $\delta^{18}O_{p}$ correlation of bobcats was slightly improved by including relative humidity in the regression ($R^2 = 0.21$, $p = 0.01$, $n = 44$). Relative humidity did show a significant modest effect on $\delta^{18}O_h$ of bobcats ($R^2 = 0.21$, $p = 0.002$, $n = 44$) but no effect on $\delta^{18}O_h$ of puma ($R^2 = 0.00$, $p = 0.818$, $n = 30$). Relative humidity, however, did not affect $\delta D_h$ of bobcats ($R^2 = 0.05$, $p = 0.146$, $n = 44$) and puma ($R^2 = 0.068$, $p = 0.164$, $n = 30$) (Table S2). The isotope composition of the analyzed hair samples spanned a range of 99.3 % for $\delta D_h$ and 12.6 % for $\delta^{18}O_h$ in bobcat, and 95.4 % for $\delta D_h$, and 18.2 % for $\delta^{18}O_h$ in puma (Figures 2 and 3). No significant relationship was found between $\delta D_h$ and $\delta D_{riv}$ for both species (bobcat: $R^2 = 0.005$, $p = 0.65$, $n = 44$; puma: $R^2 = 0.040$, $p = 0.291$, $n = 30$) (Figure 2). Likewise $\delta^{18}O_h$ and $\delta^{18}O_{riv}$ were not significantly correlated (bobcat: $R^2 = 0.030$, $p = 0.261$, $n = 44$; puma: $R^2 = 0.055$, $p = 0.211$, $n = 30$) (Figure 3). No effect of sex on the isotopic relationship between hair and water was observed for both species (Table S2). There was a weak correlation between $\delta D_h$ and $\delta^{18}O_h$ values of the same hair samples in bobcat ($R^2 = 0.195$, $p = 0.003$, $n = 43$) but not in puma ($R^2 = 0.0002$, $p = 0.939$, $n = 30$) (Figure 4). Results for the hair isotope compositions of cottontail rabbits exhibited a strong $\delta D_{riv}$ - $\delta^{18}O_{riv}$ ($\delta^{18}O_h$: $R^2 = 0.81$, $p < 0.0001$, $n = 13$) and a moderate $\delta^{18}O_{riv}$ - $\delta^{18}O_{riv}$ ($\delta^{18}O_h$: $R^2 = 0.25$, $p = 0.083$, $n = 13$) positive relationship.

**Figure 2. Hydrogen isotope values of keratin relative to river water.** Plot of $\delta D$ of hair ($\delta D_h$) from bobcat, puma and eastern cottontail rabbit as well as bone collagen ($\delta D_{bc}$) from white-tailed deer* vs. mean annual $\delta D$ of river water ($\delta D_{riv}$) (*data from [56]).

doi:10.1371/journal.pone.0024601.g002
The eastern cottontail rabbits also displayed a significant positive correlation between $\delta^{18}D_{h}$ and $\delta^{18}O_{h}$ values of the same hair samples ($R^2 = 0.571$, $p = 0.003$, $n = 13$) (Figure 4).

**Discussion**

Both puma and bobcat lacked the expected correlation between water isotopes in local water and hair, and also exhibited a complete decoupling between $\delta^{18}O_{h}$ and $\delta^{18}O_{p}$. This finding contradicted strongly with results from numerous previously published studies on keratin tissues of omnivores and herbivores. Hence, tracing the provenance of feline carnivores such as puma and bobcat based on $\delta^{18}O_{h}$ and $\delta^{18}O_{p}$ isoscapes does not appear to be possible, as individuals could not be reliably placed on $\delta^{18}O_{h}$ and $\delta^{18}O_{p}$ maps. Potential explanations for this lack of correlation between hair and ambient water isotope compositions are discussed below.

Can relative humidity affect carnivore $\delta^{18}O_{h}$ and $\delta^{18}D_{h}$?

In our study, relative humidity showed a significant modest effect on $\delta^{18}O_{h}$ of bobcats ($R^2 = 0.21$, $p = 0.002$) but not on puma ($R^2 = 0.00$, $p = 0.818$) (Table S2). Previous studies on mammalian bone phosphate showed that relative humidity controls the $\delta^{18}O_{p}$ values of herbivore species with low drinking water requirements (e.g. [30]). For example, $\delta^{18}O_{p}$ values of Australian macropods [37], rabbits and hares [44] have been shown to correlate strongly with changes in relative humidity independent of $\delta^{18}O_{h}$, whereas the $\delta^{18}O_{p}$ of North American deer [38] were influenced by both relative humidity and $\delta^{18}O_{h}$. Low humidity increases the rate of evaporation of surface water and evapotranspiration of leaf- and grass-water and thus leads to oxygen isotopic enrichment effects in plants [66,67]. Drought-tolerant animals who obtain most of their water from plants thus reflect levels of environmental humidity, in particular their $\delta^{18}O_{p}$ increases with decreasing relative humidity. However, Kohn [30] hypothesized that the importance of relative humidity diminishes with increasing trophic level. Our data support Kohn’s hypothesis that predators are less controlled by relative humidity than herbivores. Bobcat $\delta^{18}O_{p}$ compositions were weakly affected by relative humidity ($R^2 = 0.21$, $p = 0.002$), most likely because they prey upon rabbits, whose $\delta^{18}O_{p}$ compositions are humidity dependent ($R^2 = 0.86$; [44]). In contrast, puma $\delta^{18}O_{h}$ compositions were not influenced by relative humidity ($R^2 = 0.00$, $p = 0.818$), probably because they feed on white-tailed deer, whose $\delta^{18}O_{p}$ is affected by both relative humidity and $\delta^{18}O_{p}$ [38]. Unlike oxygen isotopes, $\delta^{18}D_{h}$ values of both feline carnivores were not influenced by relative humidity (bobcat: $R^2 = 0.05$, $p = 0.15$; puma: $R^2 = 0.07$, $p = 0.16$). Similar observations were made for $\delta^{18}D_{p}$ (bone collagen) of white-tailed deer by Cormie et al. [68]. We conclude that relative humidity particularly affects $\delta^{18}O_{p}$ of predators (e.g. bobcats) that feed on drought-tolerant herbivore species like rabbits. However, relative humidity did not explain the lack of a correlation between $\delta^{18}D_{h}$ and $\delta^{18}O_{p}$ observed in both felids we studied.

Does an isotopic disequilibrium between food and water affect $\delta^{18}D_{h}$?

It was documented previously [13,27], that $\delta^{18}D_{h}$ is not well correlated with $\delta^{18}D_{p}$, if [i] ingested food or water sources (e.g. exotic...
foods, marine-based diet, high altitude food or snow melt drinking water) are not isotopically related to local meteoric water and/or (ii) migration between isotopically distinct habitats takes place. We tested whether the ingested food sources (i.e. key prey species) of bobcat and puma were in disequilibrium with $\delta^2H_p$, and so caused the lack of a correlation between $H/O$ isotopes in precipitation and those in felid hair. In North America, the preferred prey species of puma is the white-tailed deer ($Odocoileus virginianus$) [69], whose $\delta^{18}O_{bP}$ of bone phosphate ($\delta^{18}Obp$) [38] and $\delta^2D_{bc}$ bone collagen values ($\delta^2Dbc$) [56] strongly correlate with $\delta^{18}O_p$ and $\delta^2D_p$, respectively (Figure 2 and 3). In contrast, bobcats mainly prey on lagomorphs [70], whose $\delta^{18}Oh$ and $\delta^2Dh$ values we also found to show a direct relationship with $\delta^{18}Op$ and $\delta^2Dp$ (Figure 2 and 3). Thus the oxygen and hydrogen isotopic composition of prey are not reflected in the hair of their respective predators. Cats are not obligate drinkers [71] and hence isotopic content of drinking water does not explain the lack of a correlation between $\delta^2D_p$ and $\delta^2Dh$ in felines.

Migration between isotopically distinct biomes during biosynthesis of hair might also affect the correlation of $\delta^2Dh$ with $\delta^2D_p$. We would have expected this effect based on potential species- or sex-specific behavioral differences characterizing our study species. Puma and bobcat, for instance, have significantly different home range sizes [2,72], which are also known to vary between seasons and sex. Although carnivores exhibit typical mammalian dispersal behaviour, where males disperse and females are philopatric [73]; we did however not observe an effect of sex on the hair/water isotope correlation for both carnivore species (Table S2). We therefore concluded that the isotopic disequilibrium of food and water does not explain the lack of a relationship between $\delta^2D_p$ and $\delta^2Dh$ observed in puma and bobcats.

**Does a carnivorous diet affect $\delta^2Dh$?**

Some studies have suggested a dietary trophic-level effect on $H$ isotope systematics of animal tissues [13,42,45,74,75]. Possibly, high levels of animal protein consumption leads to a decoupling of $\delta^2D$ in keratins from $\delta^2D_p$ and a deviation from the mean relationship between keratin $\delta^2D$ and $\delta^{18}O$ [45,76]. Diet may thus represent a confounding factor in the use of $H$ and $O$ isotopes for geographic tracking [13].

We developed a simple model of hydrogen isotope incorporation in carnivores to illustrate possible trophic-level enrichment and isotopic decoupling of $\delta^2Dh$ in carnivores. Various fractionation factors and source pools contributing to non-exchangeable hydrogen in hair were considered (Figure 5). Controlled experiments on domestic cats have shown that, on average, only 1% of their total water input originates from drinking water [71]. So, drinking water likely has minor control on deuterium enrichment in felids, leaving the isotopic input of prey as a major determinant of the isotopic signature of carnivore body water. In this aspect, strict carnivores differ significantly from herbivores and omnivores, whose body water is to a large extent (64–80%, see Table 1) obtained from drinking water (Figure 5(i)). Isotope fractionation from drinking water to body water occurs [35,42,77] and may play an important role in $\delta^2Dh$ enrichment of carnivore proteins. Feline carnivores consume prey species whose $\delta^2D_{bc}$ and $\delta^{18}Obw$ are...
expected to be higher than $\delta D_{bw}$ due to evaporative enrichment from insensible water loss through skin and breath vapor loss [34,78]. Consequently, carnivores mainly consuming deuterium-enriched prey should have higher $\delta D_{bw}$ values over those of their prey. A similar process has been documented in humans for the consumption of cow milk and the resulting enrichment in deuterium of consumer tissue [42,79]. Otherwise the consumption of D-depleted prey might decrease the carnivore $\delta D_{bw}$ values particularly during winter when prey species have built up their body fat reserves. Fat reserves are known to have significantly more negative $\delta D$ values than proteinaceous tissues [24,76,80,81]. The temporary alternation of D-depleted and enriched carnivore diets relative to $\delta D_{bw}$, based on differential seasonal consumption of lipids and proteins, respectively, might change the $\delta D_{bw}$ [35] and is finally recorded in $\delta D_h$ during carnivore hair growth [92].

Hydrogen isotope fractionation can also occur during the oxidation of food to form body water (see Figure 5 (ii)). Carnivores have the ability to digest and utilize high levels of dietary fat and protein and so produce relatively higher levels of metabolic water [54,83,84]. Catabolism of macronutrients and production of metabolic water could cause hydrogen isotope fractionation processes leading to deuterium enrichment [35,41]. In addition, isotopic fractionation most likely happens during the incorporation of body water into tissue amino acids (see Figure 5 (iii)). Water from food, drinking water and metabolism are the three source pools which can be fixed into newly synthesized non-essential amino acids [13]. However, the fraction of hydrogen fixed into amino acids may scale with the extent of non-essential amino acid synthesis in the body. This, in turn, is related to the level and amino acid composition of dietary protein intake [85]. Carnivores exhibit low levels of non-essential amino acid synthesis because their natural meat-rich diet contains all required amino acids [86]. Consequently, low levels of hydrogen fixed into amino acids in vivo could maximize the transfer of hydrogen from diet to hair thereby enhancing the contribution of isotopically heavy, prey-derived hydrogen in carnivore hair [13]. Finally, it is also possible that isotope fractionation occurs during the transfer of food amino acids to tissue amino acids (Figure 5 (iv)). $\delta D_h$ enrichment of carnivore proteins could also occur through selective catabolism of isotopically lighter amino acids [45]. We conclude that there are several possible isotopic fractionation steps during the metabolic incorporation of hydrogen into carnivore hair that could induce enrichment in deuterium and leading to higher $\delta D_h$ and a loss of correlation with $\delta D_p$.

**Effects of carnivore physiology and metabolism on $\delta D_h$ and $\delta^{18}O_h$**

If diet rather than drinking water solely controls carnivore $\delta D$, we would have expected a variation of the hair/water regression in slope and intercept compared to herbivores and omnivores. Because there was no significant correlation between oxygen and hydrogen isotope compositions of hair and precipitation and $\delta D_h$ and $\delta^{18}O_h$, we therefore suspected the dietary trophic-level effect was potentially obscured by physiological and metabolic adaptations in carnivores [87]. Animals which display deviations from the normal covariance between $\delta D$ and $\delta^{18}O$ in keratin are carnivorous fish, birds and mammals [45] and ancient human populations with a meat-rich diet [13,42,74], which all consume high levels of animal protein and fat. From a purely nutritional perspective, they are all strict carnivores. Through evolution, their adherence to a specialized meat-rich diet induced changes in their metabolic pathways and nutritional requirements [54]. These physiological and metabolic adaptations in strict carnivores could considerably affect the H and O isotope systematics of their keratins.

The H and O isotope compositions of human hair strongly covary, and are closely related to meteoric (drinking) water at the place of residence [8] with the exception of mid 20th century Inuit people [13]. Bowen et al. [13] did not find strong support for ubiquitous effects on the H/O isotope systematics of human hair related to physiological adaptations. However, in pre-globalization times, the typical diet of the Inuit contained high levels of dietary protein and fat from high trophic-level marine animals [88]. Mid 20th century Inuit people thus fed at the highest trophic level of all humans. Since marine food webs have typically longer chain lengths than terrestrial food webs [89], the consumption of marine predators may confer a trophic-level enrichment of Inuit $\delta D_h$ [13].

**Table 1.** Food and drinking water inputs of hydrogen in the body water of different organisms under laboratory conditions.

| Species            | Food (%) | Drinking water (%) | Reference |
|--------------------|----------|--------------------|-----------|
| Lab rats           | 37       | 64                 | [118]     |
| Woodrats           | 29       | 71                 | [17]      |
| Doves              | 15       | 85                 | [33]      |
| Humans             | 20       | 80                 | [34]      |
| European roe deer  | 24       | 76                 | [119]     |

**Figure 5.** Hydrogen isotope model of herbivores and carnivores. Model of hydrogen isotope physiology and the contribution of food and water to non-exchangeable hydrogen in the hair of herbivores and carnivores. Letters represent processes where isotope fractionation occurs (see text for detailed discussion). Blue coloring represents water inputs and green food inputs.

doi:10.1371/journal.pone.0024601.g005
Historic Inuit are also classified as obligate carnivores among omnivorous humans because they require nutrients that are present only in animal tissue of their diet [90] and so differ from other ancient humans who used a marine-dominated but omnivorous diet like the Ainu from Japan and Thai from Thailand [13].

Measurements of δD in feathers have been successfully applied in many bird species to estimate the origins of migrating and wintering individuals [36]. However, in strictly carnivorous raptors like Amur Falcons (Falco amurensis; [91]) and Cooper’s Hawks (Accipiter cooperii; [92]) the linkage between feather δD and δDp was weaker [93]. However, this may be complicated due to the fact that several raptors grow feathers during periods of high work associated with breeding and so may produce more deuterium enriched feathers due to evaporative water loss.

The natural diet of wild felines contains a high proportion of the energy as protein, a variable percentage as fat and a very low percentage as carbohydrate [55]. Metabolic adaptations mainly concern the loss of anabolic pathways required for the synthesis of nutrients universally present in their natural meat-based diet [94]. One of the most striking aspects here is that strict carnivores have lost the ability to produce metabolic compounds that are commonly synthesized by virtually all herbivores and omnivores. For example, cats lack the enzymatic machinery to synthesize some amino and fatty acids, thereby significantly increasing their basal requirement for proteins and essential amino acids. When ingesting prey, wild cats avoid consuming plant materials contained in the intestines [87] and hence the digestion of dietary starches and sugars has adapted to low carbohydrate intake [95].

Currently we lack a testable explanation for our observed and confounding isotopic patterns, but considering the unique feline physiology, we hypothesized that the food metabolism of strict carnivores may exert a vital effect particularly on physiology, we hypothesized that the food metabolism of strict dietary starches and sugars has adapted to low carbohydrate contained in the intestines [87] and hence the digestion of some amino and fatty acids, thereby significantly increasing their commonly synthesized by virtually all herbivores and omnivores. Lost the ability to produce metabolic compounds that are associated with breeding and so may produce more deuterium enriched feathers due to evaporative water loss.

The natural diet of wild felines contains a high proportion of the energy as protein, a variable percentage as fat and a very low percentage as carbohydrate [55]. Metabolic adaptations mainly concern the loss of anabolic pathways required for the synthesis of nutrients universally present in their natural meat-based diet [94]. One of the most striking aspects here is that strict carnivores have lost the ability to produce metabolic compounds that are commonly synthesized by virtually all herbivores and omnivores. For example, cats lack the enzymatic machinery to synthesize some amino and fatty acids, thereby significantly increasing their basal requirement for proteins and essential amino acids. When ingesting prey, wild cats avoid consuming plant materials contained in the intestines [87] and hence the digestion of dietary starches and sugars has adapted to low carbohydrate intake [95].

Recently findings from Pecquerie et al. [41] support our hypothesis. They propose two mechanisms involved in stable isotope fractionation during metabolic reactions: First, the selection of molecules for the anabolic or the catabolic pathway routes depends on their isotopic composition. Second, the concept of atom recombination recognizes that molecules are not completely disassembled into elements during chemical reactions [96]. A non-random allocation of atoms of a particular substrate (e.g. food amino acids) to a particular product (e.g. keratin amino acids) impacts isotopic composition of a given product (e.g. hair). While isotope fractionation takes place in metabolic reactions [41], these were particularly modified during the evolutionary history of carnivores. Knowing that approximately two thirds of the hydrogen in human hair are derived from food [27], we suspect that carnivores might be affected by alternate modes of isotopic routing of macronutrients into hair (Table 2).

The water metabolism in feline carnivores also differs from herbivores and omnivores. Cats drink to a limited extent [55,83] and excrete concentrated urine [97–99]. In addition they produce relatively high levels of metabolic water, which contributes on average 10% to their total water intake [54,83]. Drinking water volume, however, exerts a significant physiological control on the isotopic composition of hydrogen and oxygen in human body water [26] (Table 1). Besides various water conservation adaptations, strict carnivores have higher basal metabolic rates than other mammals [100,101]. A high metabolic rate associated with a low rate of drinking, results in a weak correlation of δ18Op with δ18Owater [25]. We infer that this applies to strict carnivores and assumed that relatively smaller contributions of oxygen in carnivore hair originate from drinking water. In addition, cats lose water primarily through panting [102] vs. from sweat glands of foot pads [103]. Differences in the isotope compositions of liquid water during sweating vs. vapor during panting should affect their body isotopic compositions. Panting animals should thus have higher δ18Op and δ18Oh values than animals that sweat because water vapour lost in panting is more depleted in 18O [30,104]. The same should apply to δ18Dwater and δ18Dp.

In contrast to the weak correlation between feline carnivore hairs δDh and δ18Oh and meteoric water δ18Op and δ18Dp (Figures 2 and 3), a good correlation between claw δDh and δ18Dp was observed in a recently published study of migrating pumas in the USA [6]. The reason why the two keratinous tissues do not reflect meteoric water values in the same way remains unclear. However, a similar paradox is known for human fingernails and hair, with nails displaying a more variable H/O isotope composition and a comparatively weaker correlation between δDp and δ18Dp [105], alternate modes of isotopic routing of macronutrients into hair and nail as well as different amino acid compositions of hair and nail [106].

### Amino acid composition of cat hair

The isotopic values of keratins are generally defined by the isotopic composition of their constituent amino acids [106]. For example, cysteine, serine and glutamate, all non-essential, metabolically active amino acids are present at very high proportions in hair [107]. Their isotopic composition reflects both food and drinking water, with a slight bias towards food. Due to the high relative abundance of non-essential amino acids, their isotopic composition can often dominate the bulk H and O isotope signature and mask the isotope composition from essential amino acids. The latter are present at lower proportions and routed directly from dietary sources [108]. The constancy of amino acid composition and hence isotopic values between tissues, even for related proteins like nail and hair, cannot be implied [106]. Large isotopic differences between amino acids of different components have been observed [109–111], reflecting their formation via different metabolic, synthetic and catabolic processes. However, the amino acid composition of cat hair protein is comparable with that of dog, horse, sheep and human hair [107]. Apparently only the proline content of cat hair protein appears to be lower and glycine appears to be higher than in the other species [107]. Variations in amino acid composition of cat hair might thus be responsible for some of the differences in isotopic patterns we have observed.

| Species | Food (%) | Drinking water (%) | Reference |
|---------|----------|-------------------|-----------|
| Woodrats | 75 | 25 | [17] |
| Japanese quail | 74–69 | 26–32 | [24] |
| House sparrow | 82 | 18 | [21] |
| Humans | 69, 64, 73a | 31, 36, 27b | [27] |

Table 2. Food and drinking water inputs of hydrogen in hair and feathers of different organisms.
Does tanning of museum skins have an effect on the H/O isotopic composition of hairs?

To our knowledge this is the first H/O isotope study on mammal hair which benefits from large museum collections as a valuable source of sample material. However, it has not been assessed whether the tanning process used for preserving hides affects the H/O isotopic composition of taxidermy skins. Tanning chemicals are intended to stop deterioration processes of the skin. At a molecular level tanning chemicals act as solid spacers, which replace the H bonds linking the polypeptide chains of the collagen fiber and thus stabilize the collagen structure of museum skins [112]. Collagen and hair are both proteinaceous tissues and interpeptide H-bonding is abundant and important for maintaining the alpha-helical structure of collagen and hair [113]. Thus, tanning chemicals could potentially alter the non-exchangeable H isotope composition of hairs. However, we hypothesize that tanning chemicals did not affect the H/O isotopic composition of the analyzed felid hairs. First, the rabbit hairs which have most likely undergone the same tanning process as felid hairs, showed good isotopic ($\delta^1$H and $\delta^{18}$O) correlation between hair and meteoric waters (Figure 2 and 3). Second, initial results from a small “before and after tanning experiment” using a common mineral tanning technique (aluminium salts [114]) on hairs from different mammal species indicated that there was no significant effect of the tanning process on the H isotopic values of these hair samples (data not shown).

Conclusions

Stable isotope (H, O) data from bobcat and puma hairs from a range of locations across North America revealed that feline carnivores cannot be placed on $\delta^{18}$O and $\delta^2$H isoscapes for forensic investigation purposes. The effective application of water isoscapes for geographic source determination of feline carnivores is most likely compromised by major controls of their diet, physiology and metabolism on $\delta^{18}$O and $\delta^2$H. However, we noted that the integration of H and O isotopes into animal proteins in general remains poorly understood. Isotope fractionation and routing during metabolic and tissue formation processes is complex and presumably varies between herbivores, omnivores and carnivores. Significant research thus remains to be performed to characterize the precise origin and sensitivities of the observed isotope signals.
