Summary: Objective: Although studies have evaluated learning curves for laparoscopic surgery (LS), this issue has not yet been addressed in gynecologic oncologists. The present study aimed to evaluate LS proficiency for early-stage endometrial cancer among gynecologic oncologists.

Methods: We examined 25 cases in which LS with pelvic lymphadenectomy (PLA) for endometrial cancer was performed by two gynecologic oncologists undergoing training in LS. The LS duration, estimated blood loss (EBL), number of dissected pelvic lymph nodes (PLNs), and perioperative complications were assessed as measures of surgical proficiency.

Results: Operators A and B performed 10 and 15 cases, respectively, with median LS durations of 348.5 and 378 minutes, respectively. Although the LS duration and number of procedures did not exhibit a significant correlation, the regression lines for both operators showed decreasing trends. Both operators had a consistently low median EBL (A, 57 ml; B, 60 ml). Operators A and B dissected a median of 21.5 and 22 PLNs, respectively. Although both operators dissected a relatively large number of PLNs, with a median of over 20 per patient after the introduction of LS, this number decreased as the number of LS increased for Operator B \( (p=0.009) \). However, no correlation was observed between the LS duration and number of PLNs dissected by Operator B \( (\rho=0.353, p=0.197) \). A severe perioperative complication, specifically perforation of the sigmoid colon requiring emergent laparotomy, occurred in one case; however, the association with surgical manipulation was not definitive.

Conclusion: The observed gynecologic oncologists were able to acquire early proficiency in LS for early-stage endometrial cancer.

Key words laparoscopic surgery, endometrial cancer, gynecologic oncologist, learning curve, safety
in laparotomy procedures for EC.

MATERIALS AND METHODS

Patients and operators

This retrospective study consisted of cases in which LS with pelvic lymphadenectomy (PLA) was performed for the treatment of EC at Kurume University Hospital between February 2015 and October 2017. The institutional review board approved the study protocol (No. 17222).

The indications of LS for EC were as follows: clinical stage IA, endometrioid carcinoma grade 1 or 2 in preoperative histology, and a uterine body smaller than a fist. Patients with a body mass index (BMI) of \( \geq 35 \) kg/m\(^2\) or with preoperatively predicted severe pelvic adhesions were excluded. All procedures were performed by two gynecologic oncologists (Operators A and B) undergoing training in LS.

Procedure of LS for endometrial cancer

All patients underwent an extended simple hysterectomy, which corresponded to the type II radical hysterectomy described in the revised Piver classification [8]. The external uterine os was sutured to avoid tumor leakage prior to the abdominal procedure. Initially, a 12-mm port was inserted through the umbilicus to enable insertion of a 10-mm video scope. Pneumoperitoneum was generated using CO\(_2\) to achieve an intraabdominal pressure of 10 mmHg. After inspecting the abdominal cavity, three ports were inserted in a modified diamond configuration: two 5-mm ports were placed 2 cm above and 2 cm medial to both sides of the superior anterior iliac spine, while a 12-mm port was placed between the pubic symphysis and umbilicus. A uterine manipulator was not used. A VagiPipe\(^{\text{TM}}\) (Hakko Co. Ltd, Chikuma, Nagano, Japan) was then introduced vaginally to identify the vaginal fornix. Hysterectomy was performed using Ligasure\(^{\text{TM}}\) Maryland (Coviden, Dublin, Ireland), monopolar and bipolar energy devices after sealing the fallopian tubes with Ligasure\(^{\text{TM}}\). After the uterine artery was separated from the ureter and ligated, the cardinal ligament was transected between the uterine artery and ureter without opening the ureter tunnel. The uterus was then placed in a Memobag\(^{\text{TM}}\) and retrieved through the vagina. The external iliac, inguinal, obturator, internal iliac, and common iliac lymph nodes were dissected via PLA, and the pelvic lymph nodes (PLNs) were retrieved through a reducer sleeve to avoid port site metastasis.

Evaluation of surgical proficiency

Surgical proficiency was evaluated using the following parameters: LS duration, estimated blood loss (EBL), number of dissected PLNs, and perioperative complications (within 4 months after LS). LS duration was defined as the time from skin incision to closure. The EBL and number of dissected PLNs were retrieved from anesthesia records and pathology reports, respectively. Perioperative complications were evaluated using the Common Terminology Criteria for Adverse Events, Version 4.0 or Clavien-Dindo Classification, Version 2.0.

For the statistical analysis, the Wilcoxon test was used to assess the surgical outcomes. The strengths of correlations were assessed using Spearman’s correlation coefficient (\(\rho\)), and the degrees of correlation were classified as weak (\(\rho=0.2-0.4\)), moderate (\(\rho=0.4-0.7\)), or strong (\(\rho=0.7-1.0\)). A P value of <0.05 was regarded as statistically significant. We used JMP software, Version 13 (SAS Institute Inc., Cary, NC, USA) for the statistical analyses.

RESULTS

Thirty-eight patients who underwent LS for diagnosed EC between February 2015 and October 2017 were studied retrospectively. PLA was performed in 25 cases, and PLN sampling was performed in nine cases. Extended simple hysterectomy and bilateral salpingo-oophorectomy were performed in two cases. A further two cases transitioned to laparotomy because of ureter injury or peritoneal dissemination of carcinoma.

The characteristics of the 25 patients who underwent PLA are summarized in Table 1. These patients had a median age of 56 years and median BMI of 24.2 kg/m\(^2\). Nine had undergone a previous laparotomy procedure. Preoperative histology revealed grades 1 and 2 EC in 23 and two cases, respectively. Regarding comorbidities, nine, eight, three, and one patient presented with obesity, hypertension, diabetes mellitus, and hyperthyroidism, respectively (including duplicates).

The surgical outcomes are summarized in Table 2. Median duration of LS was 367 minutes in total, 348.5 minutes in Operator A, and 378 minutes in Operator B. The total median EBL was 60 ml, with respective values of 57 and 60 ml for Operators A and B. The total median number of dissected PLNs was 22, with respective values of 21.5 and 22 for Operators A and B.

To evaluate LS proficiency, we compared the
number of LS performed by each operator with the LS duration, EBL, and number of dissected PLNs (Figure 1). For both operators, a moderate but non-significant correlation was observed between the number and duration of LS (Operator A: \( \rho = -0.543, p=0.105 \); Operator B: \( \rho = -0.472, p=0.076 \)). However, the regression lines indicated a decreasing trend in the LS duration. For both operators, the EBL was small and remained stable from the introduction of LS. This parameter did not correlate significantly with the number of LS performed by either operator (Operator A: \( \rho = -0.157, p=0.453 \); Operator B: \( \rho = -0.177, p=0.527 \)). However, EBL values as high as 650 ml were recorded shortly after the introduction of LS (Operator A, third case; Operator B, second case). These large blood losses were attributed to difficulty with securing the operative field in an obese patient in the former case and to iliac vein injury in the latter case.

Notably, we observed an inter-operator difference in the correlation between the number of LS performed and the number of dissected PLNs. For Operator B, the number of dissected PLNs decreased as the number of LS increased (\( \rho = 0.646, p=0.009 \)). By contrast, no significant correlations between the number of dissected PLNs and the LS duration were observed for either operator (Operator A: \( \rho = -0.085, p=0.815 \); Operator B: \( \rho = 0.353, p=0.197 \)) (Figure 2). Therefore, the reduced duration of LS was attributed to increased proficiency with LS because the duration tended to decrease irrespective of the number of dissected PLNs.

The perioperative complications are summarized in Table 3. Perioperative complications occurred in two and six cases performed by Operators A and B, respectively. One complication was serious and involved a Grade 3 perforation of the sigmoid colon in a

patient who presented with mild low abdominal pain and fever at 4 days after LS. This patient had an elevated C-reactive protein level of 18.3 mg/dl, and a subsequent computed tomography scan revealed a perforation of the sigmoid colon which was treated via emergent laparotomy. In this case, the manipulation that might have caused perforation of the sigmoid colon could not be determined from the video. However, a preoperative colonoscopy had identified multiple diverticula in the sigmoid colon, and postoperative pathology revealed chronic inflammation around these diverticula. Accordingly, the perforation of the sigmoid colon might be attributed to either the surgical manipulation or incidental diverticulitis, or both.

**DISCUSSION**

In this study of two gynecologic oncologists, we observed the development of proficiency after approximately 10 to 15 cases. Regarding safety, only one patient developed a serious complication for which a causal relationship with surgical manipulation could not be confirmed.

Studies of the proficiency of surgery often rely on the duration of the targeted procedure. Although the number of LS cases required for stabilization of the learning curve varied among studies [9-13], in this study, the duration of LS tended to decrease after 10 or 15 cases. We note that although the LS duration tended to increase from the seventh to eleventh cases performed by Operator B, cases 10 and 11 had the second-largest and largest uterine sizes of all cases in this study, and the latter case required an episiotomy for transvaginal removal. Therefore, the actual LS durations in cases 10 and 11 were relatively long (398 and 441 minutes). Notably, the inverse correlation between the number of LS performed and the duration of LS became statistically significant when case 11 was excluded from the analysis (r=-0.552, p=0.041).

Table 4 summarizes several studies that investigated the learning curve of LS for EC [9-13]. Notably, the median EBLs of 57 and 60 ml for Operators A and B in our study were extremely low when compared to those of other studies (115–325 ml) [9-13]. By contrast, Operators A and B dissected considerably higher median numbers of PLNs (21.5 and 22, respectively), compared to other studies (7.8–17.3) [9-13], and this number remained relatively higher even after consid-

erring the decrease in the number of dissected PLNs by Operator B with increasing experience. Potentially, a high level of experience with laparotomy for EC contributed to the small EBL volumes and relatively large number of dissected PLNs recorded for the operators in our study.

As noted above, a severe complication (sigmoid colon perforation) was observed in only one case. Although it was difficult to determine whether surgical manipulation or diverticulitis was the cause, this outcome underscores the importance of careful intestinal tract manipulation. Additionally, this study was limited by the retrospective design, single institution setting, and small number of cases. Potentially, a further increase in the number of LS cases may lead to further reductions in operation times and a shift in the number of cases necessary to stabilize the learning curve.

**CONCLUSION**

The achievement of proficiency with LS requires knowledge of anatomy, experience with laparotomy, and training in laparoscopic handling. Gynecologic oncologists may develop LS proficiency in a relatively shorter period, as they already possess the requisite anatomical knowledge and tend to have some experience with laparotomy.
