Analytical and numerical evaluation of the Debye and Meissner masses in dense neutral three-flavor quark matter

Kenji Fukushima

RIKEN BNL Research Center, Brookhaven National Laboratory, Upton, New York 11973, USA

We calculate the Debye and Meissner masses and investigate chromomagnetic instability associated with the gapless color superconducting phase changing the strange quark mass \( M_s \) and the temperature \( T \). Based on the analytical study, we develop a computational procedure to derive the screening masses numerically from curvatures of the thermodynamic potential. When the temperature is zero, from our numerical results for the Meissner masses, we find that instability occurs for \( A_1 \) and \( A_2 \) gluons entirely in the gapless color-flavor locked (gCFL) phase, while the Meissner masses are real for \( A_4 \), \( A_5 \), \( A_6 \), and \( A_7 \) until \( M_s \) exceeds a certain value that is larger than the gCFL onset. We then handle mixing between color-diagonal gluons \( A_1 \), \( A_8 \), and photon \( A_7 \), and clarify that, among three eigenvalues of the mass squared matrix, one remains positive, one is always zero because of an unbroken U(1)\(_A\) symmetry, and one exhibits chromomagnetic instability in the gCFL region. We also examine the temperature effects that bring modifications into the Meissner masses. The instability found at large \( M_s \) for \( A_4 \), \( A_5 \), \( A_6 \), and \( A_7 \) persists at finite \( T \) into the u-quark color superconducting (uSC) phase which has \( u-d \) and \( s-u \) but no \( d-s \) quark pairing and also into the two-flavor color superconducting (2SC) phase characterized by \( u-d \) quark pairing only. The \( A_1 \) and \( A_2 \) instability also goes into the uSC phase, but the 2SC phase has no instability for \( A_1 \), \( A_2 \), and \( A_3 \). We map the unstable region for each gluon onto the phase diagram as a function of \( M_s \) and \( T \).

I. INTRODUCTION

The rich phase structure of matter at high baryon density has attracted much interest over decades theoretically and phenomenologically. At sufficiently high density and low temperature, wherever quarks feel an attractive force as is suggested from the one gluon exchange between quarks that are antisymmetric in color, the Fermi surface of quark matter is unstable against forming a Cooper pair whose condensation leads to color superconductivity \( 1 \). It is well established that the color-flavor locked (CFL) phase is a ground state of three-flavor quark matter in the asymptotically high density region where the strange quark mass \( M_s \) is negligible as compared with the quark chemical potential \( \mu \). \( 2 \)

If it is realized in a bulk system like the cores of compact stellar objects, quark matter must be neutral in electric and color charges \( 3, 4, 5 \). As long as \( M_s/\mu \) is negligibly small, three-flavor quark matter, which is composed of the equal number of \( u, d, \) and \( s \) quarks, satisfies electric and color neutrality on its own regardless of whether it is in the normal or CFL phase. When \( M_s \) comes to have a substantial effect suppressing \( s \) quarks, there arise various possibilities in forming Cooper pairs and in achieving neutrality, that brings intricate subtleties into the phase structure especially in the intermediate density region where \( M_s \) can compete with \( \mu \).

When the system is normal quark matter, a finite electron density is required to neutralize the system electrically because the number of \( s \) quarks is reduced by \( M_s \neq 0 \). In CFL quark matter, on the other hand, neutrality can be fulfilled even without electrons rigidly at zero temperature \( 6 \) and approximately at low temperatures below an insulator-metal crossover \( 7, 8 \). This is because the BCS ansatz for Cooper pairing between cross-species of quarks enforces equality in the numbers of red, green, blue, and \( u, d, s \) quarks and thus neutrality. At zero temperature, another candidate, that is, the two-flavor color superconducting (2SC) phase, is known to cost a larger free energy than the CFL phase under the neutrality conditions, or, it could exist for strong coupling between quarks in some density windows \( 9, 10, 11 \).

Electronless and neutral CFL quark matter lasts as long as the Fermi energy mismatch when two quarks were not paired, which is given by \( M_s^2/2\mu \) as explained later, is less than the energy gap \( \Delta \). There should appear a new state of matter once the energy gain by releasing the pressure between cross-species of quarks surpasses the gap energy, which occurs when \( M_s^2/2\mu > \Delta \). Then, some of quark energy dispersion relations pass across zero and their pairing is disrupted in the corresponding momentum (blocking) region that is from one zero to another zero of the quark excitation energy. The new state is called the gapless CFL (gCFL) phase \( 12 \), and, if any other phase transitions such as the chiral phase transition and the transition to a crystalline color superconductor \( 13, 14 \) lie at lower densities than the gapless onset, the gCFL phase must show up next as the density goes down from the CFL side.

The gapless or breached pairing superconductivity was first discussed in a non-relativistic model and was recognized as an unstable state \( 12 \) and its analogue in three-flavor quark matter was considered in Ref. \( 15 \). It was discovered later on that stable gapless superconductivity could be possible under the constraint of particle number fixing in a non-relativistic model \( 16 \) (see also Ref. \( 17 \) for more discussions on stability) and of electric and color neutrality in the gapless regime of the 2SC
(g2SC) phase [16].

Besides gapless superconductivity, there is another competing possibility, i.e. the mixed phase, to realize neutrality [17, 18, 19], and if the mixed phase has a lower free energy, the gapless phase would not come to realization. According to Ref. [20], it can be the case in fact for the g2SC phase which should be taken over energetically by the mixed phase where normal and color superconducting phases coexist, and consequently the g2SC phase may be less of a reality. It must deserve further investigation, however, especially with the screening effects in the mixed phase taken into account to declare the existence or non-existence of the (g)2SC phase. In the case of the gCFL phase, on the other hand, the free energy comparison indicates that the gCFL phase should be stable energetically apart from a minor exception of the CFL-2SC mixed phase possibility, which will be presumably ruled out, however, once the surface tension and the Coulomb energy corrections are included [21]. Hence, so far, the gCFL phase remains as a likely candidate for the ground state at moderate density and is considered to be relevant to neutron star physics [22].

However, chromomagnetic instability first found in the g2SC phase [23] and later confirmed also in the gCFL phase [24, 25] implies that the gapless phase is not stable against perturbation of transverse (chromomagnetic) gluon fields and the true ground state must need something further. It is negative Meissner masses squared, i.e., imaginary Meissner masses, that the authors of Refs. [23, 24, 25] have actually revealed in the gapless phases. Since the Meissner mass is the screening mass for transverse gluons, the instability signifies spontaneous generation of the expectation value of gauge fields. Keeping in mind a simple relation in superconductors between the gauge fields and currents in the London gauge, we can regard chromomagnetic instability as color current generation. (An interpretation of instability as spontaneous baryon current generation has been argued in Ref. [26].)

To put it another way, it is possible to interpret it as instability towards a state characterized by diquark condensates with color-dependent oscillation in coordinate space [27], because gauge fields in the quark propagator generally reside in the form of the covariant derivative. This state of quark matter is a sort of crystalline color superconductors under the single colored plain wave ansatz. It should be worth emphasizing that the difference is only in intuitive pictures, and in effect, these above interpretations are equivalent, which is mathematically described by the gauge transformation. Still, anyway, it is controversial what the true ground state should be that supersedes the homogeneous gCFL phase.

The purpose of this paper is to compute the Debye and Meissner masses in the (g)CFL phase and to present detailed analyses on the nature of chromomagnetic instability which occurs in connection with the presence of gapless quarks. Our central results are condensed in the unstable regions on the phase diagram presented in Figs. 1, 2, and 3. In both the CFL and gCFL phases there is no mixing with other gluons for \( A_1, A_2, A_4, A_5, A_6, \) and \( A_7 \) respectively have the same screening masses. We shall write \( A_{1,2} \) for instance to mean whichever of \( A_1 \) or \( A_2 \) equivalently from now on. As for \( A_5, A_8, \) and the electromagnetic field \( A_\gamma, \) on the other hand, mixing between them arises and thus we have to refer to eigenvalues of the \( 3 \times 3 \) mass squared matrix to investigate instability. It should be noted that the color
The unstable regions for $A_{1,2}$ and $A_{6,7}$ are depicted in Fig. 2. In the 2SC phase there is no discrimination between $A_{4,5}$ and $A_{6,7}$ and the difference is manifested only when quark matter lies in the CFL or uSC phase. Our mapping is consistent with all of the known results both in the 2SC phase [23] and in the CFL phase [24]; no instability takes place near the gCFL onset for $A_{4,5}$ nor $A_{6,7}$, while the large $M_s^2/\mu$ regions exhibit instability which turns out to be related to the g2SC instability. At small temperatures and large $M_s^2/\mu$ the Meissner masses squared for $A_{4,5}$ and $A_{6,7}$ are negative until the system reaches the phase boundary from which the system enters the phase of unpaired quark matter (UQM).

It seems to be somewhat tricky to understand the unstable regions for mixed modes of $A_3$, $A_8$, and $A_{11}$. Figure 4 shows the unstable region enclosed with thick lines inside which the Meissner mass squared for $A_{1,2}$ is negative. The phase diagram underlaid is what has been revealed in Ref. [3] for the case of weak coupling yielding $\Delta_0 = 25$ MeV at $M_s = T = 0$. The gCFL phase starts appearing at $M_s^2/\mu = 47.1$ MeV which is well close to the kinematical estimate $(M_s^2/\mu)c \simeq 2\Delta$. In the vicinity of the phase boundary line on which one of three gaps vanishes, i.e., $\Delta_2 = 0$, there comes out a rather complicated structure which is not robust but strongly depends on a choice of the coupling strength. We will not present results for other coupling cases as done in Ref. [8], for our purpose here is not to disclose the phase structure but to argue characteristic features of chromomagnetic instability and to settle where it becomes relevant on the phase diagram.

We observe that instability grows for $A_{1,2}$ as soon as the gCFL state occurs at zero temperature. The instability penetrates from the CFL region where all $u$-$d$, $d$-$s$, and $s$-$u$ quarks make Cooper pairs into the uSC region where $u$-$d$ and $s$-$u$ quarks remain to pair, but never enters the 2SC region where only the $u$-$d$ quark pairing gap is nonvanishing. Actually in the 2SC phase, $A_{1,2}$ become irrelevant to the Higgs-Anderson mechanism, and therefore the Meissner mass for $A_{1,2}$ must be zero there.

The unstable regions for $A_{4,5}$ and $A_{6,7}$ are depicted in Fig. 3. In the 2SC phase there is no discrimination between $A_{4,5}$ and $A_{6,7}$ and the difference is manifested only when quark matter lies in the CFL or uSC phase. Our mapping is consistent with all of the known results both in the 2SC phase [22] and in the CFL phase [24]; no instability takes place near the gCFL onset for $A_{4,5}$ nor $A_{6,7}$, while the large $M_s^2/\mu$ regions exhibit instability which turns out to be related to the g2SC instability. At small temperatures and large $M_s^2/\mu$ the Meissner masses squared for $A_{4,5}$ and $A_{6,7}$ are negative until the system reaches the phase boundary from which the system enters the phase of unpaired quark matter (UQM).

The exact correspondence between the gapless and instability onsets is apparent only at zero temperature since the finite-temperature effects allow for thermal quark excitations which are not clearly distinguishable from quarks in the blocking region. An interesting manifestation of this is the unstable region in the uSC phase in which there are no gapless quarks below $T \sim 5$ MeV (see the dotted curve in the uSC region shown in Fig. 1 in Ref. [8]). In a sense, at finite temperature, we can say that the instability penetrates into gapped sides, as is also observed from Fig. 5 in Ref. [25].

We are explaining how we have come by these instability mappings in a numerical way in later discussions, starting with the following subsections in which we shall make a brief review of the gCFL phase and of the derivation of the Debye and Meissner screening masses of gauge fields. The readers who are already familiar with these basics can skip most of them and jump to Sec. II.

### A. Gapless CFL phase

Our strategy to approach the Debye and Meissner masses is based on the thermodynamic potential that has been formulated within an effective model. In the following subsections, we discuss the model and approximations to describe the gCFL phase, and then illustrate the quark excitation energies as a function of the momentum (i.e. the dispersion relations).
1. Model and approximations

In this paper we adopt essentially the same model and approximations as used in Refs. [8, 9]. The only difference is that the $M_s$ effect is incorporated as an effective chemical potential shift. This approximation is necessary to relate the Meissner mass to the potential curvature with respect to gluon source fields in a simple way. The model employed here is the Nambu–Jona-Lasinio (NJL) model with four-fermion interaction. In our model study we assume that the predominant diquark condensate is antisymmetric in Dirac indices, antisymmetric in color, and thus antisymmetric in flavor:

$$\langle \psi_i^a \gamma^5 \psi_j^b \rangle \sim \Delta_1 \epsilon^{ab_1} \epsilon_{ij1} + \Delta_2 \epsilon^{ab_2} \epsilon_{ij2} + \Delta_3 \epsilon^{ab_3} \epsilon_{ij3}, \quad (1)$$

where $(i,j)$ and $(a,b)$ represent the flavor indices $(u,d,s)$ and the color triplet indices (red, green, blue) respectively. The gap parameters $\Delta_1$, $\Delta_2$, and $\Delta_3$ describe a $9 \times 9$ matrix in color-flavor space that takes the form,

$$\Delta = \begin{pmatrix}
0 & \Delta_3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\Delta_3 & 0 & \Delta_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \Delta_1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -\Delta_3 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & -\Delta_3 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & -\Delta_2 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & -\Delta_2 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & -\Delta_1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -\Delta_1 \end{pmatrix} \quad (2)$$

in the basis $(ru, gd, bs, gu, rd, rs, bu, bd, gs)$. In the same way as in Refs. [8, 9], we ignore diquark condensates which are symmetric in color, though we know that they do not break any new symmetry and consequently can take a finite value. This approximation is motivated by the fact that the QCD interaction is repulsive between quarks in this channel and such diquark condensates have been actually known to be insignificant quantitatively [7].

In the mean-field approximation where the condensates $\bar{u}u$ are relevant, we only have to consider the four-fermion interaction in the diquark-diquark channel that can be generally handled in hand after appropriate Fierz transformation. That is,

$$\mathcal{L} = \bar{\psi} (i \gamma^\mu + \mu \gamma^5 - M) \psi + \mathcal{L}_{\text{int}}, \quad (3)$$

where

$$\mathcal{L}_{\text{int}} = \frac{G}{4} \langle \bar{\psi}^a \gamma^5 \epsilon^{ab_1} \epsilon_{ij1} \psi_j^{b_1} \rangle C \langle \bar{\psi} T^b \rangle \times \langle \psi_i^{a'} \gamma^5 \epsilon^{a'b'} \eta \epsilon_{i'j'1} \psi_j^{b'} \rangle \quad (4)$$

Here the mass matrix $M$ is unity in color and diagonal $(0,0,M_s)$ in flavor $(u,d,s)$ space in our approximation and $\mu$ the matrix of quark chemical potentials in color-flavor space. Bold symbols generally denote matrices in color-flavor space. The charge conjugation matrix is $C = i \gamma^2 \gamma^0$.

The effect of nonzero $M$ on the particle dispersion relation becomes apparent in the vicinity of the Fermi surface, where it can be well approximated by a shift in quark chemical potentials by $M^2/2\mu$. We shall make use of this prescription that actually turns out to be essential to allow us to relate the Meissner mass to the potential curvature. In the present work, as in Refs. [8, 9], $M$ is not current but constituent quark mass and is treated as an input parameter. We know that this approximation provides a correct phase structure unless the chiral phase transition cuts deeply into the gCFL region under the choice of strong coupling in the chiral sector [28].

Chemical potentials are fixed by equilibration and neutrality. Stable quark matter should be a color singlet as a whole and neutral in the electric charge under $\beta$-equilibrium. Color singletness is a more stringent condition than neutrality. It has been shown, however, that no energy cost is needed to project a neutral state onto a singlet state in color in the thermodynamic limit [29]. Hence, it is sufficient to impose global neutrality with respect to the electric and color charges. To describe that, we shall consider $\mu_e$, $\mu_s$, and $\mu_8$ that are coupled to negative $Q = \text{diag}(\frac{2}{3}, -\frac{1}{3}, -\frac{1}{3})$ in flavor $(u,d,s)$ space so that a positive $\mu_e$ corresponds to the electron density, $T_3 = \text{diag}(\frac{1}{2}, -\frac{1}{2}, 0)$, and $\sqrt{2} T_3$ is $\text{diag}(\frac{1}{2}, \frac{1}{2}, -\frac{1}{2})$ in color (red, green, blue) space, respectively. Then, 9 diagonal components of the effective chemical potential matrix $\mu_{\text{eff}}$ (including the shift by $M^2/2\mu$) in color-flavor space are explicitly

$$\begin{align*}
\mu_{ru} &= \mu - \frac{2}{3} \mu_e + \frac{1}{3} \mu_3 + \frac{1}{3} \mu_8, \\
\mu_{gd} &= \mu + \frac{1}{3} \mu_e - \frac{1}{3} \mu_3 + \frac{1}{3} \mu_8, \\
\mu_{bs} &= \mu + \frac{1}{3} \mu_e - \frac{2}{3} \mu_8 - \frac{M^2}{2\mu}, \\
\mu_{gu} &= \mu - \frac{2}{3} \mu_e - \frac{1}{3} \mu_3 + \frac{1}{3} \mu_8, \\
\mu_{rd} &= \mu + \frac{1}{3} \mu_e + \frac{1}{3} \mu_3 + \frac{1}{3} \mu_8, \\
\mu_{rs} &= \mu + \frac{1}{3} \mu_e + \frac{1}{3} \mu_3 - \frac{1}{3} \mu_8 - \frac{M^2}{2\mu}, \\
\mu_{bd} &= \mu - \frac{1}{3} \mu_e - \frac{2}{3} \mu_8, \\
\mu_{gs} &= \mu + \frac{1}{3} \mu_e - \frac{1}{3} \mu_3 + \frac{1}{3} \mu_8 - \frac{M^2}{2\mu}. \\
\end{align*} \quad (5)$$

The gap parameters corresponding to $\bar{u}u$ in this model are precisely defined as

$$\Delta_\eta = \frac{1}{2} G \langle \bar{\psi}^a \gamma^\alpha C \gamma^5 \epsilon^{\alpha \beta \gamma} \epsilon_{iijj} \psi_j^\beta \rangle \quad (6)$$

With all these definitions, if we choose Nambu-Goldstone basis as $\Psi(p) = (\psi(p), C \psi^\dagger(-p))^T$, we can express the mean-field (inverse) quark propagator in a simple form,

$$i S^{-1}(p) = \begin{pmatrix}
\not{p} + \mu \gamma^0 & i \gamma_5 \Delta \\
i \gamma_5 \Delta & -\not{p} + \mu \gamma^0
\end{pmatrix} \quad (7)$$
after rearranging the Dirac matrices. The quark propagator is a \(72 \times 72\) matrix in color, flavor, spin, and Nambu-Gor’kov space. From zeros of the inverse propagator, we can read 72 energy dispersion relations \(\varepsilon_i(p)\). The thermodynamic potential \(\Omega\) is thus written in terms of \(\varepsilon_i\)’s as

\[
\Omega = -\frac{1}{8\pi^2} \int_0^\Lambda dp p^2 \sum_{j=1}^{72} \left\{ |\varepsilon_i| + 2T \ln \left( 1 + e^{-|\varepsilon_i|/T} \right) \right\}
\]

with the electron contribution in the last three terms. In order to fix three gap parameters and three chemical potentials at each \(M_i\), \(\mu\), and \(T\), we will simultaneously solve three gap equations,

\[
\frac{\partial \Omega}{\partial M_1} = \frac{\partial \Omega}{\partial M_2} = \frac{\partial \Omega}{\partial M_3} = 0,
\]

and three neutrality conditions,

\[
\frac{\partial \Omega}{\partial \mu_e} = \frac{\partial \Omega}{\partial \mu_3} = \frac{\partial \Omega}{\partial \mu_8} = 0.
\]

Here \(\Lambda\) is the ultraviolet cut-off parameter and we use \(\Lambda = 800\) MeV as in Refs. 3, 4, 5. The coupling constant \(G\) is chosen to yield \(\Delta_0 = 25\) MeV when both \(M_i\) and \(T\) are zero. In the present work we take the quark chemical potential \(\mu = 500\) MeV that roughly corresponds to 10 times the normal nuclear density in the model.

When \(M_i\) is not so large as to disrupt any Cooper pair, \(\mu_e, \mu_3, \text{ and } \mu_8\) satisfying electric and color neutrality have been analyzed at zero temperature in a model-independent way 4. Two of three can be fixed as a function of the third that we will choose \(\mu_e\) here, then

\[
\mu_3 = \mu_e,
\]

\[
\mu_8 = -\frac{M_2^2}{2\mu} + \frac{\mu_e}{2}.
\]

The important feature of the CFL phase we should note is that the thermodynamic potential 5 at \(T = 0\) with the electron contribution disregarded is independent of

\[
\mu_\tilde{Q} = -\frac{3}{4} \left( \mu_e + \mu_3 + \frac{3}{2} \mu_8 \right)
\]

that is the chemical potential for \(\tilde{Q} = Q - T_3 - \sqrt{3} T_8\). It is known that \(\tilde{Q}\) is a generator of the “rotated electromagnetism” that is never broken by any condensate of the form 11. At zero temperature \(Q\)-charged excitations in CFL quark matter are all gapped and the CFL phase is a \(Q\)-insulator 12.

In the presence of the electron contribution to the thermodynamic potential, in reality, there is a gentle curvature on the plateau of the thermodynamic potential provided by the last three terms in 5 which select \(\mu_e = 0\), meaning zero electron density. Although it makes only slight changes in energy, the existence of the electron effects is crucial in understanding the \(A_{1,2}\) instability.

2. Gapless dispersion relations

Since the gap matrix 3 is block-diagonal, the \(72 \times 72\) quark propagator matrix is block-diagonal as well in color-flavor space and can be divided into four parts; one \(24 \times 24\) part for \(ru-gd-bs\) quark pairing with \(\Delta_1, \Delta_2\), and \(\Delta_3\) and three \(16 \times 16\) parts for quark pairing of \(bd-gs\) with \(\Delta_1, rs-bu\) with \(\Delta_2\), and \(gu-rd\) with \(\Delta_3\). It might be possible but quite hard to handle the \(24 \times 24\) part analytically. Fortunately, as we will see shortly, this \(24 \times 24\) intricate part has little to do with chromomagnetic instability, so we will limit our discussion here to the propagator for \(bd-gs, rs-bu,\) and \(gu-rd\) pairings.

Leaving the explicit expression of the quark propagator until Sec. III let us elucidate here the quark energy dispersion relations obtained from zeros of the inverse propagator. In general for the \(16 \times 16\) pair involving two species \(A\) and \(B\) quarks the energy dispersion relation takes the form,

\[
\varepsilon_{A-B} = \sqrt{(p - \bar{\mu}_{A-B})^2 + \Delta_{A-B}^2} + \delta \mu_{A-B},
\]

\[
\bar{\varepsilon}_{A-B} = \sqrt{(p + \bar{\mu}_{A-B})^2 + \Delta_{A-B}^2} + \delta \mu_{A-B}
\]

for quasi-particle and antiparticle excitations respectively, where \(\bar{\mu}_{A-B} = \frac{1}{2}(\mu_A + \mu_B)\) and \(\delta \mu_{A-B} = \frac{1}{2}(\mu_A - \mu_B)\) and \(\Delta_{A-B}\) is the energy gap for \(A-B\) pairing. In our definition \(\delta \mu_{A-B} = -\delta \mu_{B-A}\). Gapless dispersion relations come about once

\[
|\delta \mu_{A-B}| > \Delta_{A-B}.
\]

Then, using effective chemical potentials 3 with the known CFL solutions 11 and 12, we have

\[
\delta \mu_{gu-rd} = \frac{1}{2} \mu_e - \frac{1}{2} \mu_3 = -\mu_e,
\]

\[
\delta \mu_{rs-bu} = \frac{1}{2} \mu_e + \frac{1}{2} \mu_3 + \frac{1}{2} \mu_8 - \frac{M_2^2}{4\mu} = \mu_e - \frac{M_2^2}{4\mu},
\]

\[
\delta \mu_{bd-gs} = \frac{1}{2} \mu_3 - \frac{1}{2} \mu_8 + \frac{M_2^2}{4\mu} = \frac{M_2^2}{2\mu},
\]

and

\[
\bar{\mu}_{gu-rd} = \bar{\mu}_{bd-gs} = \bar{\mu}_{rs-bu} = \mu - \frac{M_2^2}{4\mu}
\]

in the CFL phase. If it were not for the electron terms in the thermodynamic potential, \(\mu_e\) could lie anywhere as far as it does not disrupt the pairing of \(gu-rd\) nor \(rs-bu\) quarks which are \(Q\)-charged. In the region between the dashed and dot-dashed curves shown in Fig. 4 the system remains to be a \(Q\)-insulator, meaning the bandgap. The CFL solution ceases to exist at the point where these two curves meet, before which a first-order phase transition to unpaired quark matter takes place as indicated by the dotted vertical line (see discussions in Ref. 12 for details).

By substituting \(\mu_e = 0\), as is favored in the CFL phase with electrons, for the above expressions, we readily realize that the \(bd-gs\) and \(rs-bu\) dispersion relations are identical supposing \(\Delta_1 = \Delta_2 = \Delta\). In fact, the \(bd-gs\) and
rs-bu quark pairings are breached at the same time when

$$|\delta \mu_{\text{bd-gs}}| = |\delta \mu_{\text{rs-bu}}| = \frac{M_s^2}{2 \mu} > \Delta, \quad (21)$$

which corresponds to the fact that in Fig. 4 the solid and dashed lines cross at $\mu_e = 0$. This coincidence of the gapless onset locations for bd-gs and rs-bu quarks is responsible for instability for $A_{1, 2}$ in the gCFL phase, as only $A_{1, 2}$ can excite a pair of rs and gs quarks at once (see Fig. 5). In other words, if the electron terms are absent and $\mu_e$ is chosen to be positive, say $\sim 10$ MeV, the $A_{1, 2}$ instability would disappear, while there would remain the instability for other gluons.

Once quark matter enters the gCFL phase with larger $M_s^2/\mu$ than the onset, the bd-gs and rs-bu quark dispersion relations are both gapless but no longer degenerated. The blocking momentum region for bd-gs quarks becomes wider with increasing $M_s^2/\mu$ as shown by the solid curve in Fig. 5 and $\Delta_3$ decreases accordingly because quarks within the blocking region cannot participate in pairing. Since rs and bu quarks have nonzero $\bar{Q}$-charge, the blocking momentum region for rs-bu quarks is not allowed to be arbitrarily wider and is determined by the requirement to cancel $\bar{Q}$-charge brought by electrons whose density is $\sim \mu_e^2$. That means, the width of the blocking momentum region for rs-bu quarks is estimated as $\delta p \sim \mu_e^2/3\mu^2 \ll \mu$. The actual form of the rs-bu dispersion relation is, as a result, kept to be almost quadratic with a tiny blocking region anywhere in the gCFL phase as seen by the dashed curve in Fig. 5.

Although the ru-gd-bs part is hard to anticipate a priori, there is no gapless mode involved in this sector. The dotted curve in Fig. 5 represents one of energy dispersion relations for ru-gd-bs quarks that has the lowest energy among them. It is clear from the figure that ru-gd-bs quarks are all gapped at $M_s^2/\mu = 80$ MeV and it is also the case for larger $M_s^2/\mu$. Hence, the three (solid, dashed, and dot-dashed) lines drawn for bd-gs, rs-bu, and gu-ru quarks respectively in Fig. 5 suffice for judging if gapless quarks are present or not.

### B. Debye and Meissner screening masses

In a medium at finite temperature and density the gauge fields are screened by the polarization of charged thermal excitations. The screening effect on the gauge fields differs depending on the longitudinal and transverse directions due to the lack of Lorentz invariance. The screening mass, which is the inverse of the screening length, in the longitudinal direction is called the (chromo)electric or Debye screening mass, and in (color) superconductors in particular the transverse screening mass, the (chromo)magnetic or Meissner screening mass in QED (QCD). In the normal phase any perturbative calculation leads to vanishing magnetic mass in the static limit. In the superconducting phase, on the other hand, a finite magnetic screening mass results from the Higgs-Anderson mechanism and embodies the Meissner effect so that superconductors can exclude the magnetic field.

The Debye and Meissner masses are calculated from
the eigenvalues of the mass squared matrix in color defined by the self-energies;
\[ m_{D,\alpha\beta}^2 = -\lim_{q \to 0} \Pi_{\alpha\beta}^{(0)}(\omega = 0, q), \]  
\[ m_{M,\alpha\beta}^2 = \frac{1}{2} \lim_{q \to 0} (\delta_{ij} - \bar{q} i \gamma_j) \Pi_{\alpha\beta}^{(1)}(\omega = 0, q), \]  
(22, 23)
where \((\alpha, \beta)\) represent the color octet (or photon) indices and we defined \(\bar{q} = \bar{q}' / \bar{q}\), and \(\Pi_{\alpha\beta}^{(1)}\) is the self-energy with the Lorentz indices \((\mu, \nu)\) for the gluons \((\alpha, \beta \leq 8)\) or photon \((\gamma)\) instead of \(\alpha, \beta\) or their mixing. (We always use the subscript \(\gamma\) for the sake of meaning photon.) At the one-loop level at high density, the quark loop contributions for all eight gluons. Here \(m^2\) the Lorentz indices \((\mu, \nu)\) and we defined \(\Pi_{\alpha\beta}^{(1)}\), which is proportional to \(\mu^2\), is predominant, so we shall consider only the polarization tensor coming from one-loop diagrams of quarks.

In the symmetric CFL state with \(M_s = 0\), the mass squared matrix is diagonal in color and all eight gluons have the same screening mass. The Debye and Meissner masses in a color superconductor have been calculated diagrammatically in Ref. [30] and we shall quote the results here;

\[ m_D^2 = \frac{21 - 8 \ln 2}{6} m_g^2 \approx 2.576 m_g^2, \]  
\[ m_M^2 = \frac{1}{3} m_D^2 \approx 0.859 m_g^2 \]  
(24, 25)
for all eight gluons. Here \(m_g^2 = g^2 \mu^2 / 6 \pi^2\) and \(g\) is the strong coupling constant. Note that our definition of \(m_g^2\) is different by a factor \(N_f = 3\) from the definition given in Ref. [30].

Once mixing between gluons and photon, which exists among \(A_8\) and \(A_\gamma\) in the CFL phase at \(M_s = 0\), and generally among \(A_3\), \(A_8\), and \(A_\gamma\) for \(M_s \neq 0\), is taken into account, the screening masses are to be modified. They actually have been evaluated analytically only when \(M_s = 0\) [31] and after diagonalization two eigenvalues composed of \(A_8\) and \(A_\gamma\) read

\[ \tilde{m}_{D,ss}^2 = \left(1 + \frac{4 \epsilon^2}{3 g^2}\right) m_D^2, \]  
\[ \tilde{m}_{M,ss}^2 = \left(1 + \frac{4 \epsilon^2}{3 g^2}\right) m_M^2, \]  
\[ \tilde{m}_{D,\gamma\gamma}^2 = \tilde{m}_{M,\gamma\gamma}^2 = 0, \]  
(26, 27, 28)
where \(\epsilon\) is the electromagnetic coupling constant. The last relation [28] follows from the facts that the condensates [14] leave a U(1)\(_Q\) symmetry unbroken (that is; \(\tilde{m}_{M,\gamma\gamma}^2 = 0\)), and that the system is a \(\bar{Q}\)-insulator in which \(\bar{Q}\)-charged excitations are all gapped (that is; \(\tilde{m}_{D,\gamma\gamma}^2 = 0\)).

For later convenience we shall carefully look into how these analytical expressions [24] and [26] are structured from distinct contributions of particles and antiparticles. When quarks are massless, the quark propagator can be specifically separated into the particle and antiparticle parts (see Eq. [11]). At the quark one-loop level, the gluon or photon self-energies consist of the particle-particle, particle-antiparticle, and antiparticle-antiparticle excitations. (In the case of the normal phase the particle-particle excitations in the vector channels would be to be articulated as the particle-hole excitations.) The last contribution from only the antiparticle excitations is just negligible so that we shall always omit it in our discussion.

In the \(2 \times 2\) space of Nambu-Gor’kov doubling, the quark propagator has not only the diagonal (normal) components but also the off-diagonal (abnormal) components proportional to the gap \(\Delta\) that connect two quasi-particles.

The Debye mass arises only from the particle-particle contribution. It can be further divided into the Nambu-Gor’kov diagonal and off-diagonal parts as follows;

\[ m_D^2 = [m_D^2]_{\text{diag}} + [m_D^2]_{\text{off}}, \]  
(29)
where

\[ [m_D^2]_{\text{diag}} = \frac{9}{2} m_g^2, \]  
\[ [m_D^2]_{\text{off}} = -\left(1 + \frac{4}{3} \ln 2\right) m_g^2. \]  
(30, 31)
The sum of these two parts properly reproduces [24] as it should.

In evaluating the Meissner mass, on the other hand, it is essentially important to note that the particle-antiparticle excitation produces a significant contribution comparable to the particle-particle one. The Meissner mass consists of the diagonal and off-diagonal parts,

\[ m_M^2 = [m_M^2]_{\text{diag}} + [m_M^2]_{\text{off}}, \]  
(32)
that is further split into the particle-particle (p-p) and particle-antiparticle (p-a) parts,

\[ [m_M^2]_{\text{diag}} = [m_M^2]_{\text{diag}(p-p)} + 2 [m_M^2]_{\text{diag}(p-a)} \]  
(33)
with

\[ [m_M^2]_{\text{diag}(p-p)} = -\frac{1}{3} [m_D^2]_{\text{diag}}, \]  
\[ [m_M^2]_{\text{diag}(p-a)} = \frac{3}{2} m_g^2, \]  
(34, 35)
and

\[ [m_M^2]_{\text{off}} = [m_M^2]_{\text{off}(p-p)} = \frac{1}{3} [m_D^2]_{\text{off}}, \]  
(36)
from which we can easily make sure \(m_M^2 = \frac{1}{3} m_D^2\) as is well-known in the CFL phase [30] [32]. The particle-antiparticle contribution in the off-diagonal part \([m_M^2]_{\text{off}(p-a)}\) is vanishingly small, so we dropped it off from the above relations.

It is of great importance to realize that the diagonal p-p contribution to the Meissner mass is negative one third of the Debye mass counterpart, while the p-a excitations
provide a positive contribution that is twice larger than the p-p’s. Adding them together we finally acquire the Meissner mass contribution that is positive one third of the Debye mass contribution. In the off-diagonal part, in contrast, the situation is much simpler and the ratio is positive one third itself.

In other words, in the diagonal part, the p-p loops always tend to induce paramagnetism, while diamagnetism originates from the p-a loops. Usually in the superconducting phase, the diamagnetic tendency is greater enough to bring about the Meissner effect. In gapless superconductors, however, antiparticles are never gapless and only the p-p loops are abnormally enhanced due to gapless quarks and their large density of states near the Fermi surface causes the opposite phenomenon to the Meissner effect, i.e., chromomagnetic instability. Also, this can be seen from the relations (54) and (55) which hold in the presence of finite $M_s$ or even in the gCFL phase. In the gCFL phase, a large density of states leads to a large Debye mass. Then, through (54) and (55), it should be accompanied by a large negative contribution to the Meissner mass squared, which eventually results in chromomagnetic instability.

As for (56), because the $M_s$ dependence of antiparticle excitations is suppressed by $M_s/\mu$, the relation is hardly changed for any $M_s \ll \mu$.

II. COMPUTATION OF SELF-ENERGIES

In this section we shall diagrammatically compute the calculable parts of one-loop self-energies for gluons and photon and derive the analytical expression for the singular part of the Debye and Meissner masses.

Using the mean-field quark propagator $S(p)$, and the vertex matrices, $\Gamma_{\alpha}^\nu$, in color, flavor, spin, and Nambu-Gor’kov space, we can write the one-loop self-energies in a general form as

$$-i\Pi_{\alpha\beta}^{\nu\rho}(q) = \frac{1}{2} \int \frac{d^4p}{(2\pi)^4} \text{tr} \Gamma_{\alpha}^\nu S(q + p) \Gamma_{\beta}^\rho S(p) .$$

The vertices $\Gamma_{\alpha}^\nu$ take a matrix form,

$$\Gamma_{\alpha}^\nu = \begin{bmatrix} -ig\gamma^\mu T_\alpha & 0 \\ 0 & ig\gamma^\mu T_\alpha \delta_{ij} \end{bmatrix}$$

for gluons ($\alpha = 1, \ldots, 8$) where $T_\alpha$ are the SU(3)$_{\text{color}}$ generators defined by the Gell-Mann matrices in color space and normalized as $\text{tr} T_\alpha T_\beta = \frac{1}{2} \delta_{\alpha\beta}$. For photon the vertex reads

$$\Gamma_{\gamma}^\nu = \begin{bmatrix} -ie\gamma^\mu Q_{ij} & 0 \\ 0 & i e\gamma^\mu Q_{ij} \end{bmatrix} ,$$

which is unity in color. We see that the flavor is not changed at any vertices but the color can be converted through the off-diagonal components in $T_1$, $T_2$, $T_4$, $T_5$, $T_6$, and $T_7$. We call the gluons corresponding to $T_3$ and $T_8$ as the color-diagonal gluons.

The quark propagator is divided into the particle and antiparticle parts by the energy projection operators $\Lambda^\pm = \frac{1}{2} (1 \pm \gamma^0 \cdot \vec{p})$. The explicit propagator in the bd-gs sector, for instance, can be written down after some rearrangement of the Nambu-Gor’kov (1,2) (where 2 is assigned to the Nambu-Gor’kov doublet in our convention) and color-flavor (bd,gs) indices, that is, in the basis (bd-1,gs-2,gs-1,bd-2), we have

$$-iS(p) = \begin{bmatrix} \Lambda^-_p & 0 & 0 & 0 \\ 0 & \Lambda^+_p & 0 & 0 \\ 0 & 0 & \Lambda^-_p & 0 \\ 0 & 0 & 0 & \Lambda^+_p \end{bmatrix} \gamma^0 \begin{bmatrix} S^a_{bd-gs}(p) & 0 \\ 0 & S^a_{gs-bd}(p) \end{bmatrix}$$

$$+ \begin{bmatrix} \Lambda^+_p & 0 & 0 & 0 \\ 0 & \Lambda^-_p & 0 & 0 \\ 0 & 0 & \Lambda^+_p & 0 \\ 0 & 0 & 0 & \Lambda^-_p \end{bmatrix} \gamma^0 \begin{bmatrix} S^p_{bd-gs}(p) & 0 \\ 0 & S^p_{gs-bd}(p) \end{bmatrix} ,$$

where the antiparticle part is

$$S_{A,B}^a(p) = \frac{1}{(p_0 + \varepsilon_{A,B}) (p_0 - \varepsilon_{B,A})} \begin{bmatrix} p_0 - (p + \mu B) & -i\Delta_1 \gamma_5 \gamma^0 \\ -i\Delta_1 \gamma_5 \gamma^0 & p_0 + (p + \mu A) \end{bmatrix} ,$$

and the particle part is

$$S_{A,B}^p(p) = \frac{1}{(p_0 + \varepsilon_{A,B}) (p_0 - \varepsilon_{B,A})} \begin{bmatrix} p_0 - (p - \mu B) & -i\Delta_1 \gamma_5 \gamma^0 \\ -i\Delta_1 \gamma_5 \gamma^0 & p_0 - (p - \mu A) \end{bmatrix} .$$

In this representation the structure of the Dirac indices becomes much simpler and is given by $\Lambda^\pm, \gamma^0$ and $\gamma_5 \gamma^0$ attached with $\Delta$. Then, it is important to notice that the $(\mu, \nu)$ dependence in the integrand of (57) comes from the trace over the Dirac indices alone, that is

$$\mathcal{T}_{\text{diag}}^{\mu\nu}(p; q) = \text{tr} [\gamma^\mu \Lambda^+_p \gamma^0 \gamma^\nu \Lambda^+_p \gamma^0] ,$$

for p-p and p-a loops made of the Nambu-Gor’kov diagonal components of the propagator (11) and (12). For the Nambu-Gor’kov off-diagonal components we have likewise:

$$\mathcal{T}_{\text{off}}^{\mu\nu}(p; q) = \text{tr} [\gamma^\mu \Lambda^+_q \gamma^0 \gamma^\nu \Lambda^+_p \gamma^0] ,$$

A. Singularities in $A_{1,2}$

We will first discuss $A_1$ and $A_2$ that are degenerated. The generators in color, $T_1$ and $T_2$, have a non-vanishing component only between red and green and the flavor
kept unchanged at the vertices, so that the self-energy for \( A_{1,2} \) stems from four diagrams;

\[
\Pi_{11}^{\mu\nu} = \Pi_{\text{diag}(rg;s)}^{\mu\nu} + \Pi_{\text{diag}(rg;u)}^{\mu\nu} + \Pi_{\text{diag}(rg;d)}^{\mu\nu} + \Pi_{\text{off}(ru-gd;gu-rd)}^{\mu\nu}.
\]

Here, \( \text{diag}(rg;s) \) means the quark loop composed of the diagonal component of \( rs \) and \( gs \) quarks (see Fig. 6) and \( \text{diag}(rg;u) \) and \( \text{diag}(rg;d) \) should be understood in the same manner. The last contribution, \( \text{off}(ru-gd;gu-rd) \), represents the self-energy contribution from the off-diagonal components of \( ru-gd \) and \( gu-rd \) propagation, that is, the loop made up with \( ru \) quarks turning into \( gd \) and \( rd \) quarks turning into \( gu \) as shown in Fig. 7.

In the case of \( A_1 \) (and \( A_2 \) equivalently) only \( \Pi_{\text{diag}(rg;s)}^{\mu\nu} \) may contain gapless quarks in the gCFL phase in both lines of the loop diagram, and is expected to provide a singular contribution. As a matter of fact, the singular part presumably dominates over the screening mass behavior near the gapless onset as a function of \( M_s \). This expectation is confirmed by the comparison between functional forms of only the \( rs-gs \) polarization and the full result derived from the potential curvature we are dealing with in the next section. From Fig. 6 taking in the full results in advance, we can clearly observe that the physics near the gCFL onset is to be described by the \( rs-gs \) excitation only.

The Debye screening mass, or \( \Pi^{00} \), has only the particle-particle part (and the antiparticle-antiparticle part that is negligible) because \( \mathcal{T}_{\text{diag}(p-a)}^{00}(p;0) = \mathcal{T}_{\text{off}(p-a)}^{00}(p;0) = 0 \) and is written as

\[
\Pi_{\text{diag}(rg;s)}^{00}(q;0) \rightarrow 0
\]

\[
\frac{-g^2}{8\pi^2} \int dp \, p^2 \mathcal{T}_{\text{diag}(p-p)}^{00}(p;0) \mathcal{U}_{\text{diag}(rg;s)}(p),
\]

where \( \mathcal{T}_{\text{diag}(p-b)}^{00}(p;0) = 2 \) and we defined

\[
\mathcal{U}_{\text{diag}(rg;s)} = \mathcal{F}_{p-p}[\varepsilon_{bu-rs}; bd, gs, bu] + \mathcal{F}_{p-p}[-\varepsilon_{rs-bu}; bd, gs, bu] + \mathcal{F}_{p-p}[\varepsilon_{bd-gs}; bu, rs, bd] + \mathcal{F}_{p-p}[-\varepsilon_{gs-bd}; bu, rs, bd].
\]

The p-p integrand \( \mathcal{F}_{p-p} \) is explicitly given by

\[
\mathcal{F}_{p-p}[\varepsilon_{A,B}; C, D, E] = \frac{[\varepsilon_{A,B} + (p-\mu_E)] [\varepsilon_{A,B} + (p-\mu_C)]}{\varepsilon_{A,B} + \varepsilon_{A,B} - \varepsilon_{C,D}} \tanh \left( \frac{\varepsilon_{A,B}}{2T} \right)
\]

with the energy dispersion relation \( \varepsilon_{A,B} \) defined in (15).

In the CFL phase, as we have already mentioned, the \( bd-gs \) and \( rs-bu \) quark dispersion relations are identical and there are vanishing combinations in the denominator of (50) like \( \varepsilon_{gs-bd}(q + p) - \varepsilon_{rs-bu}(p) \rightarrow 0 \) as \( q \rightarrow 0 \). The numerator goes to zero in the same limit of \( q \rightarrow 0 \) and consequently it amounts to the derivative with respect to \( \varepsilon \) acting onto the distribution function, i.e., \((\partial/\partial \varepsilon_{A,B}) \tanh[\varepsilon_{A,B}/2T] \). At zero temperature this is proportional to the delta function \( \delta(\varepsilon_{A,B}) \) that takes a finite value only when gapless quarks (that is, \( \varepsilon_{A,B}(p) = 0 \) for some \( p \)) are present.

Using the solution (11) and (12) and assuming \( \Delta_1 = \Delta_2 = \Delta \) that is known to be a good approximation in the CFL phase, the polarization at zero temperature can simplify as

\[
\Pi_{\text{diag}(rg;s)}^{00} = -\frac{g^2}{4\pi^2} \int dp \, p^2 \delta^2 \left( \frac{\varepsilon - (p-\mu)}{2\varepsilon} \right) \delta \left( \frac{\varepsilon - M_s^2}{2\varepsilon} \right) + \Delta^2 \left( \frac{\varepsilon - M_s^2}{2\varepsilon} \right)
\]
with $\bar{\mu} = \mu - M_s^2/6\mu$ and $\varepsilon = \sqrt{(p - \bar{\mu})^2 + \Delta^2}$. This expression is valid only up to the onset where the gCFL starts. Actually, right at the onset where $M_s^2/2\mu = \Delta$, the energy dispersion relation for $gs$-$bd$ and $rs$-$bu$ quarks is quadratic near the Fermi momentum and approximated as $\varepsilon(p) - M_s^2/2\mu \approx (p - \bar{\mu})^2/2\Delta$. Then, the $p$-integration for the first term of (51) picks up the density of states at $p = \bar{\mu}$ and ends up with an infrared divergence. We would emphasize that this singular behavior originates from the electron pressure which ensures $\mu_e = 0$. Otherwise, two quarks running through the loop diagram would not be gapless simultaneously at the gCFL onset.

In the CFL region before the gCFL occurs, it is rather the second term of (51) which is a major contribution, which can be further approximated as

$$\Pi_{\text{diag}(r; s)}^{00} = -\frac{g^2\mu^2}{4\pi^2} = -\frac{3}{2}m_g^2$$

with any logarithmic divergence neglected. The logarithmic terms are, in fact, given by $\sim \Delta^2 \ln[\Lambda/\Delta]$ that is much smaller than the leading terms of $\bar{\mu}$ and corrections are $\sim 1\%$ for our choice of $\Lambda = 800$ MeV and $\Delta_0 = 25$ MeV. We will always drop any logarithmic terms $\sim \ln[\Lambda/\Delta]$ throughout this paper.

Hence, the contribution to the Debye mass in the CFL side is obtained as

$$[m_M^2]_{\text{diag}(r; s)} = \frac{3}{2}m_g^2.$$  \hfill (53)

Interestingly enough, this result exactly corresponds to one-flavor contribution (i.e. one-third) of (30) and does not have $M_s$-dependence until the gCFL onset.

We can immediately extend our discussion to the Meissner mass once if we analyze the $(\mu, \nu)$ structure in the polarization. The $p$-$p$ contribution to the Meissner mass is

$$\frac{1}{2}(\delta_{ij} - \hat{q}_i\hat{q}_j)T_{\text{diag}(p-p)}^{ij}(p; 0)$$

$$= \frac{1}{2}(\delta_{ij} - \hat{q}_i\hat{q}_j) \times 2\vec{p}\cdot\vec{p'} = 1 + (\hat{q} \cdot \vec{p})^2$$ \hfill (54)

In the third line we made use of averaging over the angle integration that leads to one third, that is, $\int d^3p (\hat{q} \cdot \vec{p'})^2\mathcal{U}(p) = \frac{1}{3} \int d^3p \mathcal{U}(p)$. In evaluating the Debye and Meissner masses $\Delta_{\text{diag}(r; s)}(p)$ is common, so that from the above relation we reach the general relation,

$$[m_M^2]_{\text{diag}(r; s)} = -\frac{1}{3}[m_D^2]_{\text{diag}(r; s)}.$$  \hfill (55)

that is completely consistent with (31).

The $p$-$a$ part generates ultraviolet divergent terms proportional to $\Lambda^2$, $\Delta^2 \ln[\Lambda/\Delta]$, and $(M_s^2/\mu)^2 \ln[\Lambda/\Delta]$ (32). In the present work, as in the treatment of the Debye mass, we ignore any logarithmic divergences. We can rewrite $f_{p-p}$ into $f_{p-a}$ immediately, in view of the difference between (41) and (42), by replacing corresponding $\varepsilon_{A-B}$ by $\varepsilon_{A-B}$, and $p-\mu_A$ by $-(p+\mu_A)$. A similar analysis to (31) on the Dirac trace part leads to a factor as follows:

$$\frac{1}{2}(\delta_{ij} - \hat{q}_i\hat{q}_j)T_{\text{diag}(p-a)}^{ij}(p; 0)$$

$$= \frac{1}{2}(\delta_{ij} - \hat{q}_i\hat{q}_j) \times 2[\delta^{ij} - \vec{p}\cdot\vec{p'}] = 1 + (\hat{q} \cdot \vec{p})^2 \rightarrow \frac{4}{3}$$ \hfill (56)

Then, after some calculations along the same line as Refs. 23, 30 with the approximation that $\Delta$ and $M_s$ are all neglected, we acquire

$$[m_M^2]_{\text{diag}(r; s)} = \frac{1}{2} \lim_{q \rightarrow 0} (\delta_{ij} - \hat{q}_i\hat{q}_j) [\Pi_{\text{diag}(r; s)}^{ij}(p-a)]$$

$$\approx \frac{1}{2}m_g^2 - \frac{\Lambda^2}{12\pi^2},$$

that is consistent with (34) divided by the flavor factor $N_f = 3$ up to the ultraviolet divergence.

After all, the sum over the $p$-$p$, $p$-$a$, and $a$-$p$ parts finally amounts to

$$[m_M^2]_{\text{diag}(r; s)} = [m_M^2]_{\text{diag}(r; s)} + 2 \times [m_M^2]_{\text{diag}(r; s)} + \text{(subtraction)}$$ \hfill (58)

in the CFL phase, where “subtraction” is a term added by hand to remove the $\Lambda^2$-term which should be renormalized. Eq. (57) indicates

$$\text{(subtraction)} = \frac{\Lambda^2}{6\pi^2}$$ \hfill (59)

per one polarization diagram of Nambu-Gor’kov diagonal particle-antiparticle excitations that should contain ultraviolet divergences.

\section{No singularities in $A_{4,5}$ and $A_{6,7}$}

The analyses in the previous subsection give us information about the origin of singularities around the gCFL onset. When two quarks involved in the loop diagram becomes gapless at the same time, the divergent density of states compels us to face the imaginary Meissner mass. We can easily comprehend that this kind of singularity near the gapless onset is absent for $A_{4,5}$ and $A_{6,7}$.

The self-energies are diagrammatically decomposed as

$$\Pi_{44}^{\mu\nu} = \Pi_{\text{diag}(br; s)}^{\mu\nu} + \Pi_{\text{diag}(br; u)}^{\mu\nu} + \Pi_{\text{diag}(br; d)}^{\mu\nu} + \Pi_{\text{off}(bu-rs; ru-bs)}^{\mu\nu}$$ \hfill (60)

and

$$\Pi_{66}^{\mu\nu} = \Pi_{\text{diag}(gb; s)}^{\mu\nu} + \Pi_{\text{diag}(gb; u)}^{\mu\nu} + \Pi_{\text{diag}(gb; d)}^{\mu\nu} + \Pi_{\text{off}(gd-br; bd-gs)}^{\mu\nu}.$$ \hfill (61)
None of these above polarizations is composed of would-be gapless quarks only, i.e. $bd$-$gs$ and $rs$-$bu$ quarks only. Therefore, we can conclude at this stage of analyses that $A_{4,5}$ and $A_{8,7}$ do not exhibit chromomagnetic instability at least in the vicinity of the gCFL onset.

C. Singularities in $A_{3,8,7}$

For color-diagonal gluons $A_3$, $A_8$, and photon $A_7$, neither color nor flavor is changed at the vertices. This means that 9 diagonal and 6 off-diagonal diagrams are possible. For example, the self-energy for $A_8$, for instance, has two types of singularities: one is associated with the $bd$-$gs$ gapless quark dispersion relation,

$$\Pi_{88}^{\mu
u}_{bd-gs} = \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(gg; s)} + \frac{4}{3} \Pi^{\mu\nu}_{\text{diag}(bb; d)} - \frac{2}{3} \Pi^{\mu\nu}_{\text{off}(bd-gs; bd-gs)}, \tag{62}$$

and the other is associated with the $rs$-$bu$ gapless quark (almost quadratic) dispersion relation,

$$\Pi_{88}^{\mu
u}_{rs-bu} = \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(rr; s)} + \frac{4}{3} \Pi^{\mu\nu}_{\text{diag}(bb; u)} - \frac{2}{3} \Pi^{\mu\nu}_{\text{off}(rs-bu; rs-bu)}, \tag{63}$$

The one-loop diagrams corresponding to $\Pi^{\mu\nu}_{\text{diag}(bb; d)}$ and $\Pi^{\mu\nu}_{\text{off}(bd-gs; bd-gs)}$ are shown in Figs. 9 and 10 to take some examples.

For completeness, we shall enumerate the rest here. The non-singular contributions to the $A_8$ polarization are

$$\Pi_{88}^{\mu
u}_{\text{non-singular}} = \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(rr; u)} + \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(rr; d)} + \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(gg; u)} + \frac{1}{3} \Pi^{\mu\nu}_{\text{diag}(gg; d)} + \frac{4}{3} \Pi^{\mu\nu}_{\text{diag}(bb; s)} \tag{64}$$

The diagonal contributions, as shown in Fig. 9, are easily available from the previous results only by replacing the color-flavor indices appropriately and adding $\frac{1}{3}$ to adjust the combinatorial factor. It should be noted that instability occurs in this case whenever any of quarks becomes gapless because two virtually excited quarks are identical in the color-diagonal channels.

The off-diagonal expression is also deduced simply by means of proper arrangement of the color-flavor indices and replacement of the numerator of (51) as $\varepsilon_{AB, \pm (p - \mu_B)} \rightarrow -i \Delta_{AB}$. Because $\varepsilon_{A, B, \pm (p - \mu_B)} \simeq \Delta_{AB}$ in the vicinity of the Fermi surface $p = \mu$ that is dominating over the $p$-integration, the functional form of the off-diagonal contribution is essentially the same as the diagonal contributions. There are two important features to remark here, though.

First, the self-energy contributions coming from the off-diagonal loop are free from ultraviolet quadratic divergence even in $p$-$a$ excitations. It is because the off-diagonal propagator is proportional to $\sum_{i,j} \Pi^{\mu\nu}_{ij} (p_i - p_j)^2$, but $\Delta_{AB}$ that is not rising with increasing $p$. Thus, the subtraction term proportional to $\Lambda^2$ is no longer necessary.

Second, from the trace over the Dirac indices (46) and (47), we notice that

$$\mathcal{T}^{ij}_{\text{off}} = -\mathcal{T}^{ij}_{\text{diag}}, \tag{65}$$

$$\mathcal{T}^{ij}_{\text{off}} = \mathcal{T}^{ij}_{\text{diag}}, \tag{66}$$

for both $p$-$p$ and $p$-$a$ cases, that means the diagonal and off-diagonal diagrams contribute to the Debye and Meissner masses differently. Using (55), (57) and from a similar analysis to (54), we immediately see the relation,

$$M^2_{M, \text{off}}(bd-gs; bd-gs) = \left[ m_D^2 \Pi^{\mu\nu}_{\text{off}(bd-gs; bd-gs)} \right], \tag{67}$$

that is consistent with (54). The sign difference between (55) and (67) originates from the negative sign in (55). The $p$-$a$ off-diagonal contribution to the Meissner mass squared turns out to be negligible.

In addition, the negative sign difference between (55) and (66) can explain the results for the “neutral” and “charged” condensates discussed in a two-species model in Ref. 25. As we have mentioned above, the functional form of $\Pi^{\mu\nu}_{\text{diag}(gg; s)}$, $\Pi^{\mu\nu}_{\text{diag}(bb; d)}$ and $\Pi^{\mu\nu}_{\text{off}(bd-gs; bd-gs)}$ are almost identical up to the combinatorial factor $\frac{1}{3}$. Let’s consider the “neutral” case fictitiously following
the argument in Ref. 25, for which we assume that bd and gs quarks had the opposite charge corresponding to the two-species model composed of bd and gs. Then, the polarization related to the screening masses would be \( \Pi^{\mu\nu} = \Pi^{\mu\nu}_{\text{diag}(gg; s)} + \Pi^{\mu\nu}_{\text{diag}(bb; d)} - \Pi^{\mu\nu}_{\text{off}(bd; gs; bd; gs)} \).

From (65) we see that the Debye mass positively diverges at the gapless onset, while the singularities in the Meissner mass cancel to vanish. In the “charged” case, on the other hand, we assume that bd and gs quarks had the same charge. In the same way, the polarization leading to the screening masses would be \( \Pi^{\mu\nu} = \Pi^{\mu\nu}_{\text{diag}(gg; s)} + \Pi^{\mu\nu}_{\text{diag}(bb; d)} + \Pi^{\mu\nu}_{\text{off}(bd; gs; bd; gs)} \). Obviously, the Debye mass has no singularity at the gapless onset, but the Meissner mass negatively diverges. This is exactly what was found in Ref. 25. In QCD, however, the diquark condensate is actually a mixture of the “neutral” and “charged” condensates and the Debye and Meissner masses both diverge positively and negatively from the common origin at the gCFL onset.

As a final remark of this section, we shall draw attention to the contrasting difference between the singular parts \( \Pi_{bb} \) related to bd-gs quarks and \( \Pi_{(gs)gs} \) related to rs-bu quarks. In general, the Meissner mass negatively diverges on the bd-gs, rs-bu, and gu-rd boundary lines drawn in Fig. 8. When \( M_s \) grows larger, as seen in Fig. 6, the blocking region of the bd-gs dispersion relation becomes wider and the singular character in \( \Pi_{bb} \) weakens. In contrast, \( \mu_e \) is kept to be very close to the rs-bu line in Fig. 4, for all \( M_s \) and in all the gCFL region \( \Pi_{gs} \) remains to provide a negatively huge contribution to the Meissner mass. If it were not for electrons, \( \mu_e \) would be within the bandgap and \( \Pi_{gs} \) would not be singular at all. In this sense, the singularity of \( \Pi_{gs} \) is induced by the presence of the electron terms which force \( \mu_e \) to stay in the singular region slightly below the dashed line in Fig. 4. To evaluate that huge contribution correctly from \( \Pi_{gs} \), it is essential to resolve a tiny blocking region \( \delta \mu \sim \mu_e^3/3\mu^2 \) with a great accuracy, which is next to impossible technically.

Although the strength of singularities \( \Pi_{bb} \) and \( \Pi_{gs} \) at the gCFL onset is exactly equal at \( T = 0 \), the temperature dependence is drastically different; as seen from Fig. 11, \( \Pi_{bb} \) is no longer singular even at \( T = 0.5 \) MeV. This is because at finite temperature rs-bu quarks not from the blocking region but from thermal excitations can cancel the \( Q \)-charge driven by electrons. There needs not to be a blocking region associated with rs-bu quarks. Actually, the rs-bu quark density is estimated as \( \sqrt{2\pi T} \mu^2/\pi^2 \) when its dispersion relation is quadratic, and it can balance out the electron density \( \mu_e^3/3\pi^2 \) even at \( T = (\mu_e^3/3\mu^2)/2\pi T \) that is as tiny as \( \sim \) eV for \( \mu_e \sim 1 \text{ few MeV} \). Consequently there is no gapless rs-bu quarks any more already at tiny temperatures.

![FIG. 11: Each contribution from possible singular diagrams at \( T = 0 \) and 0.5 MeV. In the figure bd-gs and rs-bu represent contributions to the Meissner mass from \( [\Pi_{bb}]_{bd-gs} \) and \( [\Pi_{gs}]_{rs-bu} \).](image)

### III. POTENTIAL CURVATURE

In order to derive the information on the full evaluation of screening masses, let us elaborate a numerical method based on the previous analytical consideration to compute the Debye and Meissner masses here. It is well-known that the Debye mass can be expressed as the potential curvature as follows

\[
m^2_{\mu\alpha\beta} = \frac{\partial^2 \Omega_\mu}{\partial \mu_\alpha \partial \mu_\beta},
\]

where \( \mu \)'s are the color chemical potential coupled to the generators \( T_\alpha \). That means, \( \mu \)'s here involve off-diagonal components in color-flavor space besides \( \mu_8 \). The thermodynamic potential defined with all \( \mu \)'s is denoted by \( \Omega_\mu \) here. The potential curvature \( \Omega_\mu \) is evaluated at vanishing \( \mu \)'s except \( \mu_3 \) and \( \mu_8 \) which are fixed by the color neutrality conditions. In QCD at finite temperature, moreover, pure gluonic loops produce a Debye mass \( \sim gT \), which is not included in Eq. 68.

All we have to know to evaluate the thermodynamic potential are the energy dispersion relations that are much easier than calculating the loop integral \( \Omega_\mu \) directly. We show the Debye masses as a function of \( M_\mu^2/\mu \) inferred from \( \Omega_\mu \) in Figs. 12 and 13. The singular behavior associated with the gapless onset emerges in an upward direction, that is accounted for from the relation (34). In other words, through the relation (34), the positively rising results for the Debye masses squared imply negative Meissner masses squared for \( A_{1,2} \) and \( A_{3,8,\gamma} \) around the gCFL onset and for all the gluons for large \( M_\mu^2/\mu \). It is worth noting that the \( Q \)-photon has a finite Debye mass for large \( M_\mu^2/\mu \) because the system in the gCFL phase has a nonzero density of electrons that can
and photon

A

constant is chosen to be with mixing turned off by hand. The electromagnetic coupling three eigenvalues, and dotted curves are the Debye masses than a realistic value, to make visible the mixing effect of A

where "bare" means the Meissner mass squared with

\[ T \text{ (dot-dashed) obtained from the potential curvature at } T = 0. \]

FIG. 12: Debye mass for the color-diagonal gluons \( A_3, A_8 \) and photon \( A_7 \), at \( T = 0.5 \text{ MeV} \). Three solid curves represent three eigenvalues, and dotted curves are the Debye masses with mixing turned off by hand. The electromagnetic coupling constant is chosen to be \( e/g = 1/2 \), which is presumably larger than a realistic value, to make visible the mixing effect of \( A_7 \).

Once we develop a relation connecting the thermodynamic potential to the Meissner mass like the above relation (68) with respect to the Debye mass, we can numerically compute the Meissner mass including not only the singular parts but also all the contributions. As a matter of fact, we have found a relation,

\[ (m^2_{M,\alpha\beta})_{\text{bare}} = \frac{1}{3} \sum_{i=1}^{3} \partial^2 \Omega_{A_i} \bigg|_{A=0}, \] 

where "bare" means the Meissner mass squared with terms diverging like \( \sim \Lambda^2 \), and \( \Omega_A \) is the thermodynamic potential defined in the presence of the gauge fields \( A_i \) (Note that bold symbols stand for matrices in color-flavor space in our notation.) in the Lagrangian (3) as

\[ \mathcal{L}_A = \bar{\psi} (i\gamma^\mu + \mu_{\text{eff}} \gamma^\rho - \vec{A} \cdot \vec{\gamma}) \psi + \mathcal{L}_{\text{int}}. \] 

Equation (69) needs some more explanation. It should be worth mentioning that (69) is a well-known general relation if we do accomplish the angle integration with respect to the loop momentum \( p \). However, this is technically difficult, for \( p \) makes an angle with \( A_i \) on evaluating \( \Omega_A \). The benefit of (69) is that we can reduce the \( p \)-integration into a one-dimensional \( p_3 \)-integration as if the rotational symmetry were not affected by \( A_i \). We shall take advantage of this simplification at the price of treating \( M_s \) as chemical potential shifts.

This relation can be proved in the following way. When the momentum \( p \) in the loop-integral is chosen to be in the 3-direction, we can show that,

\[
\begin{align*}
T^{11}_{\text{diag}(p-p)}(p;0) &= T^{22}_{\text{diag}(p-p)}(p;0) = 0, \\
T^{33}_{\text{diag}(p-p)}(p;0) &= 2, \\
T^{11}_{\text{diag}(p-a)}(p;0) &= T^{22}_{\text{diag}(p-a)}(p;0) = 2, \\
T^{33}_{\text{diag}(p-a)}(p;0) &= 0,
\end{align*}
\]

indicating that \( \Pi^{33} \) contains only the p-p contribution and \( \Pi^{11} \) and \( \Pi^{22} \) the p-a contribution. From these expressions in the same way as (54) we eventually arrive at the relation,

\[ m^2_{M,\alpha\beta} = \frac{1}{3} \left[ \Pi^{11}_{\alpha\beta}(0,0) + \Pi^{22}_{\alpha\beta}(0,0) + \Pi^{33}_{\alpha\beta}(0,0) \right]. \] 

We should remark that, even though we do not know an explicit expression for the ru-gd-bs quark propagator, the \( (\mu, \nu) \) structure comes out only through the energy projection operators and the above argument is generally valid for any quark propagator as long as \( M_s \) can be treated as an effective chemical potential shift. The relation (72) is readily rewritten in terms of the thermodynamic potential, which leads us to (69).

In our model study, the four-fermion interaction is non-renormalizable and \( \Omega_A \) suffers ultraviolet divergent terms proportional to \( \Lambda^2 \). Thus the Meissner masses derived directly from the potential curvature should have those divergences to be subtracted properly by hand. As argued in the previous analytical study, we conjecture that the subtraction term is simply inferred by counting divergent diagrams, which results in;

\[
\begin{align*}
m^2_{M,\alpha\alpha} &= (m^2_{M,\alpha\alpha})_{\text{bare}} + 3 \times \frac{g^2 \Lambda^2}{6\pi^2}, \quad (1 \leq \alpha \leq 8) \quad (73) \\
m^2_{M,\gamma\gamma} &= (m^2_{M,\gamma\gamma})_{\text{bare}} + 4 \times \frac{e^2 \Lambda^2}{6\pi^2}, \quad (74) \\
m^2_{M,\alpha\beta} &= (m^2_{M,\alpha\beta})_{\text{bare}}, \quad (1 \leq \alpha \neq \beta \leq 8) \quad (75) \\
m^2_{M,\alpha\gamma} &= (m^2_{M,\alpha\gamma})_{\text{bare}}. \quad (76)
\end{align*}
\]
and 17 to the known analytical estimates. In view of these all determined simply from the diagrammatic counting of the Nambu-Gor’kov diagonal p-a loops and the associated subtraction \( S \) with proper coefficients. In the case of \( A_8 \) for example, the divergence factor in unit of \( \Lambda^2/6\pi^2 \) coming from \( (3) \) is \( \frac{1}{2} \times \frac{1}{2} + \frac{1}{2} \) where \( \frac{1}{2} \) is a combinatorial factor. In the same way \( (6) \) and \( (4) \) give \( \frac{1}{2} \) and \( \frac{5}{3} \) respectively. The sum of these results in \( 3 \times (\Lambda^2/6\pi^2) \) as in \( (17) \). It is interesting to see that the divergent terms cancel each other in the color-mixing and photon-mixing channels. From these above expressions we have obtained the results as presented in Figs. 14, 15, and 16.

Now, before addressing the instability problem, let us compare our numerical results shown in Figs. 14, 15, and 16 to the known analytical estimates. In view of our results at \( M_s = 0 \), all the gluons except \( A_8 \) have the identical Meissner mass \( 0.892 m_g^2 \) which is consistent with \( (24) \). We have confirmed that the agreement becomes better for larger \( \mu \gg \Delta \) because the analytical estimates require this. The mixing channel with \( \epsilon/g = 1/2 \) (chosen presumably larger than realistic values to make the mixing effects apparently visible) results in \( 1.18 m_g^2 \) for \( A_8 \) and zero for \( A_1 \), which is also consistent with the analytic estimate \( \tilde{m}_g \left[ M_{8,88} \right] = 1.15 m_g^2 \) from \( (27) \). All these suggest that our method works well.

Figure 14 shows the Meissner mass squared for \( A_{1,2} \) as a function of \( M_s^2/\mu \), and is located near the onset condition given kinematically \( (M_s^2/\mu)_k \simeq 2\Delta \). (We chose the model parameters to yield \( \Delta_0 = 25 \text{ MeV} \) for \( M_s = 0 \).) We see that the Meissner mass squared is negative in the entire gCFL region at zero temperature, that means chromomagnetic instability. The zero temperature behavior for \( A_{1,2} \) is consistent with the results reported in Ref. \( (24) \) except for the asymptotic property that the Meissner mass in Fig. 14 does not approach zero for large \( M_s^2/\mu \) as it does in Ref. \( (24) \). The singularity around the gCFL onset is drastically smeared by the temperature effect as seen in the curve for \( T = 0.5 \text{ MeV} \), though chromomagnetic instability still exists for \( M_s^2/\mu > 84 \text{ MeV} \) at higher temperatures, as shown by the \( T = 5 \text{ MeV} \) curve, the Meissner screening mass smoothly goes to zero with increasing \( M_s^2/\mu \) since the system then comes to reach

FIG. 14: Meissner mass squared for \( A_{1,2} \) as a function of \( M_s^2/\mu \) at the temperatures \( T = 0 \) (solid), 0.5 MeV (dashed), and 5 MeV (dot-dashed). The vertical dotted line represents the gCFL onset. The model parameters are chosen to yield \( \Delta_0 = 25 \text{ MeV} \) at zero temperature and zero strange quark mass. The solution of the coupled equations ceases to exist at \( M_s^2/\mu = 144.7 \text{ MeV} \) and 140.5 MeV for \( T = 0 \) and 0.5 MeV respectively.

FIG. 15: Meissner mass squared for \( A_{4,5} \) as a function of \( M_s^2/\mu \) at \( T = 0 \) (solid), 5 MeV (dashed), and 10 MeV (dot-dashed).

FIG. 16: Meissner mass squared for \( A_{6,7} \) as a function of \( M_s^2/\mu \) at \( T = 0 \) (solid), 5 MeV (dashed), and 10 MeV (dot-dashed).
FIG. 17: Meissner mass squared for three eigenmodes composed of $A_3$, $A_8$, and $A_7$ as a function of $M_s^2/\mu$ at $T = 0.5$ MeV. The electromagnetic coupling constant is chosen to be $e/g = 1/2$. The dotted curves are for $A_3$, $A_8$, and $A_7$ with mixing among them turned off.

The Meissner masses corresponding to $A_3$, $A_8$, and $A_7$, as we have exposited before, are negatively divergent if any of quark excitation energies take the quadratic form as a function of the momentum. This situation takes place only at the gCFL onset. The results inside the gCFL regime are negatively large but not divergent actually. In fact a finite density of electrons requires an almost but not exactly quadratic dispersion relation anywhere in the gCFL phase. The outputs accordingly have severe dependence on the precise form of the almost quadratic dispersion relation, that is, the deviation from the quadratic form, which is hard to evaluate numerically with an extreme accuracy. We have confirmed the above mentioned behavior quantitatively in our calculations, that is, negatively large Meissner masses squared for $A_3$, $A_8$, and $A_7$ in the entire gCFL region, but we could not reduce tremendous numerical ambiguity. Instead of tackling numerical difficulties that would be milder at finite temperature, we have calculated the Meissner masses at $T = 0.5$ MeV. In Fig. 17, the dotted curves are the masses without mixing taken into account and the solid curves are the eigenvalues of the $3 \times 3$ mass squared matrix. We clearly see that instability certainly occurs in one or two of three eigenmodes. Furthermore, we note that any effect of the almost quadratic dispersion relation cannot be perceived from the $T = 0.5$ MeV results because it is already smooth enough at that temperature as is obvious also in Fig. 11.

The unstable regions read from these figures are to be considered as slices with $T$ fixed on the phase diagram. It is instructive to compile all these slices and map respective unstable regions onto the phase diagram. Figure 11 is one example to locate the phase boundary and the unstable region and to see them on a common basis. In this way we clarified the unstable regions on the phase diagram as we have already discussed at the beginning of this paper.

IV. SUMMARY AND OPEN QUESTIONS

In summary, in dense neutral three-flavor quark matter, we figured out the computational procedure to derive the Debye and Meissner screening masses from curvatures of the thermodynamic potential with respect to gluon source fields. We investigated chromomagnetic instability by changing the temperature $T$ and the Fermi momentum mismatch $M_s^2/\mu$ and explored the unstable regions for respective gluons and photon on the phase diagram involving the (g)CFL, uSC, and (g)2SC phases.

We can say that the instability lines we added on the renewed phase diagram tell us, at least, at what $\mu$ or $M_s$ the homogeneous (g)CFL, uSC, and (g)2SC phases remain to be stable at a certain $T$. From the present work, however, we cannot extract any clue about what is
going on inside the unstable regions. One possible solution
would be a crystalline-like phase as is suggested in
the two-flavor case [27]. If this is true also in three-flavor
quark matter, it is most likely that the instability lines
are to be regarded as the boundaries that separate the
homogeneous and crystalline superconducting phases. In
this sense, the boundaries drawn by thick lines in Figs. 1
and 3 have a definite physical meaning even after a true
ground state inside the unstable regions will be identi-
fied. Strictly speaking, once chromomagnetic instability
occurs in any gluon channel, it would affect the other
gluon channels. Consequently instability lines with re-
spect to one gluon going inside the unstable region with
respect to another gluon might be substantially different
from what we have seen in this work. They are actually
the most outer boundaries only that separate the homo-
ogeneous and crystalline phases, as shown in Fig. 19.

Our approach here is essentially along the same line
as in Ref. 8, and so this work leaves the open questions enumerated in Ref. 8; how gauge field fluctua-
tions affect the critical point and the order of re-
spective phase transitions 32, what the nature of \( K^0 \)-condensation in the gCFL phase is and how it affects instability 33, 37, what difference the ’t Hooft (instanton)
interaction makes that induces an interaction like
\( \sim |\Delta s|^2 M_s \), where the chiral phase transition is located and how our \( (M_s^2/\mu-T) \) phase diagram is mapped onto the \((\mu-T)\) plane with \( M_s \) solved dynamically.

In addition to these above mentioned issues, we should
make an improvement how to take account of \( M_s \) fully.
The derivation of our formula 67 needs the energy pro-
jection operator for massless quarks and works out as
long as the \( M_s \) effects can be well-approximated by a
chemical potential shift. From this reason, we could
not augment the phase diagrams for stronger couplings
(Figs. 16 and 17 in Ref. 32 for example) with the insta-
ability lines. The improvement could be implemented by
the full angle-integration in \( p \) to acquire \( \Omega_A \).

From the theoretical point of view, logarithmic diver-
gences that have been simply neglected in the present
work must be taken seriously. In particular, logarithmic
terms depending on \( M_s \) seem to remain even in the nor-
mal phase 33, while in our work the Meissner masses
turn out to be zero properly in the normal phase, sug-
gesting some cancellation mechanism between \( M_s \) depend-
dent divergences. This must be further investigated in
a field-theoretical way. Another problem of theoretical
interest is how much singularities are inhibited by non-
perturbative resummation. However small the coupling
constant \( g \) is, the polarization is divergently large at the
one-loop level, and generally, that demands a sort of re-
summation, for instance, by means of the ladder approx-
imation. The instability might not be cured itself by
resummation, but the singularities near the gCFL onset
would be possibly smoothened.

Phenomenologically, since not only the gCFL but also
the g2SC phase is within our scope especially once we
will be able to approach the stronger coupling case, it is
inevitable to examine the competition between the mixed
and crystalline phases around the g2SC region. The en-
tanglement between these phase possibilities should play
an important role to complement the phase diagram for
the large \( M_s \) or moderate density region 33.
