(Dated: May 2, 2014)

We study smectic-liquid-crystal order in a cell with a heterogeneous substrate imposing surface random positional and orientational pinnings. Proposing a minimal random elastic model, we demonstrate that, for a thick cell, the smectic state without a rubbed substrate is always unstable at long scales and, for weak random pinning, is replaced by a smectic glass state. We compute the statistics of the associated substrate-driven distortions and the characteristic smectic domain size on the heterogeneous substrate and in the bulk. We find that for weak disorder, the system exhibits a three-dimensional temperature-controlled phase transition between a weakly and strongly pinned smectic glass states akin to the Cardy-Ostlund phase transition. We explore experimental implications of the predicted phenomenology and suggest that it provides a plausible explanation for the experimental observations on polarized light microscopy and x-ray scattering.

I. INTRODUCTION

A. Motivation and background

Research on ordered condensed matter systems subject to bulk random heterogeneities has been an active field. Considerable progress has been made, providing a better understanding of real materials, where quench disorder is always present [1–8]. Recently, attention has turned to systems where the heterogeneity is confined to a surface, e.g., nematic [9–11] and smectic-liquid-crystal cells [12] with dirty substrates. These surface disordered systems are of considerable interest and exhibit phenomenology qualitatively distinct from their bulk disordered counterparts.

The commonly observed Schlieren texture [13] is a manifestation of such surface pinning in nematic cells. Recent studies also include photo alignment and dynamics in self-assembled liquid crystalline monolayers [14, 15], as well as memory effects and multistability in the alignment of nematic cells with a heterogeneous random anchoring substrate [16]. The existence of the corresponding phenomena in smectic liquid crystals has been recently revealed in ferroelectric smectic-C cells in a bookshelf geometry [17, 18]. This latter system exhibits long-scale smectic layer distortions, driven by collective random surface pinning, and awaits a detailed theoretical description.

A schematic of such a smectic-liquid-crystal cell is illustrated in Fig. 1 with a “dirty” front substrate imposing two types of surface disorders: surface random orientational pinning of local nematic order and surface random positional pinning of smectic layers. Generically, such surface pinning leads to elastic and plastic smectic disordering, latter characterized by proliferation of topological defects, e.g., dislocations. In this paper, we focus on the simpler limit of weak disorder, where the topological defects are either not present at long scales or are sufficiently dilute, whereby they can be neglected for a range of experimentally relevant length scales. Clearly this leaves a rich and challenging regime of strong pinning to future studies.

B. Summary of the results

We explore surface pinned smectic cell, focusing on the bookshelf geometry [with the coordinate system shown in Fig. 1] where y is perpendicular to the substrate and
points into the cell, $x$ (along smectic layer) and $z$ (along smectic layer normal) are parallel to the substrate. As we will show in Sec. VIII in the homeotropic geometry, the effects of random substrate reduce to that of a random-field $xy$ model in $(d - 1)$ dimensions, and are significantly less strong than in this more common bookshelf geometry.

Using a harmonic elastic description of smectic liquid crystal order with surface quenched disorder, which characterizes a thick smectic cell subject to surface heterogeneities, we studied the distortion of the smectic layers on the surface, characterized by Larkin (Imry-Ma)-like length scales given by $\xi_x$, $\xi_z \sim \xi^2 / \lambda$ that relates the distortion along the layer normal ($z$) and parallel to the layer ($x$) from either random orientational or random positional pinning, where $\lambda = \sqrt{K/B}$ is the standard smectic-liquid-crystal length, typically comparable to the layer thickness $a$ [21]. In the regime of dominant surface orientational pinning we find (with $\Delta_f$ the associated mean-squared pinning strength)

$$\xi^f_x = c B^2 \lambda^3 a^2 \Delta_f \approx \sqrt{\lambda \xi^f_x}. \quad (1)$$

For the dominant surface positional disorder (of mean-squared strength $\Delta_x$) we instead find

$$\xi^x_x = \left( 3c B^2 \lambda^3 a^2 \Delta_x \right)^{1/3} \approx \sqrt{\lambda \xi^x_x}, \quad (2)$$

where $c = 4\pi^2\approx 34.6$. In the presence of both types of surface disorders, the domain size is determined by a combination of these two lengths as discussed later in Sec. [VIII]

Adapting the standard Imry-Ma-Larkin analysis to the problem at hand, we find that long-range smectic order on the heterogeneous substrate is unstable against surface random orientational pinning in a $d$-dimensional system with $d < d^{f}_{lc}$, where

$$d^{f}_{lc} = 4, \quad (3)$$

and for the surface random positional pinning in a $d$-dimensional system with $d < d^{p}_{lc}$, where

$$d^{p}_{lc} = 6. \quad (4)$$

Thus, on sufficiently long scales, long-range smectic order in a three-dimensional cell is unstable to arbitrarily weak random pinning of statistically isotropic (nonrubbed) substrate. Below these lower critical dimensions arbitrarily weak pinning destabilizes long-range smectic order. Within the resulting finite smectic domains the correlations of smectic layer distortions grow as a power law of in-plane separation and decay exponentially into the bulk of the cell, with the characteristic length at depth $y > \xi_x$ set by $y$ itself.

We employed the functional renormalization group (FRG) [22-26] to assess the effectively strong nonlinear pinning physics on scales beyond the smectic domain size. The most interesting and potentially experimentally relevant prediction of this analysis is a three-dimensional (3D) Cardy-Ostlund-like (CO) phase transition at a temperature $T_g$ from a weakly disordered smectic for $T > T_g$ (where on long scales the surface positional pinning is averaged away by thermal fluctuations) to a low-temperature disorder-dominated smectic-glass for $T < T_g$. In the latter phase, the positional disorder flows to a CO fixed line at which the correlations of layer distortions asymptotically are characterized by the orientational pinning alone, but with an effective strength additively enhanced with $(T_g - T)^2$. The high- and low-temperature phases are distinguished by (among other features) the effective temperature-dependent orientational pinning strength

$$\delta_f(T) \equiv \Delta_f(T)/\Delta_f, \quad (5)$$

given by

$$\delta_f(T) = \begin{cases} 
1, & \text{for } T > T_g, \\
1 + \frac{a}{8\pi^2} \xi^f_x \left( 1 - \frac{T}{T_g} \right)^2, & \text{for } T \leq T_g.
\end{cases} \quad (6)$$

The long-scale smectic layer correlations on the substrate (at $y = 0$) are characterized by $C(x, z) = \langle |u_0(x, z) - u_0(0, 0)| \rangle^2$, the full behavior of which is given in Eq. (103) with limits:

$$C(x, z) \approx \begin{cases} 
\frac{\pi a^2}{\xi_x(T)}, & \text{for } x \gg \sqrt{\lambda \xi_x}, \\
\frac{2\pi}{\sqrt{\lambda \xi_x(T)}}, & \text{for } x \ll \sqrt{\lambda \xi_x},
\end{cases} \quad (7)$$

with the temperature dependent sizes

$$\xi_x(T) = \xi^f_x / \delta_f(T), \quad (8)$$

$$\xi_z(T) = \xi^f_z / \delta_f(T). \quad (9)$$

These predictions remain valid only on scales shorter than the distance between unbound dislocations and the scale $\xi^{NL}_x$ (for weak pinning), beyond which the nonlinear elasticity may become important.

We also study various experimental features of our predictions for the polarized light microscopy. We suggest that the highly anisotropic domain (as shown in Fig. D) induced by surface disorder is a plausible explanation for the commonly observed stripes in thin smectic cells [15]. We further argue that the 3D smectic glass transition predicted above (illustrated in Fig. E) may have already been observed as the aforementioned precipitous x-ray peak broadening in cooled smectic liquid crystal cells with a random substrate [17-15], which is expected to have a peak width proportional to $\xi^{-1}_x(T)$, as shown in Fig. F. Although further systematic detailed studies are necessary to test this conjecture, based on the robustness of our theoretical prediction, we expect this transition to be quite generic in smectic liquid crystal cells with heterogeneous substrates.

The remainder of this paper is organized as follows. In Sec. [ XI ] we present a simple model of a thick
II. MODEL

A. Bulk elasticity

We will focus on a smectic cell in the experimentally and theoretically more interesting bookshelf geometry.

(half-infinite) bookshelf smectic cell with surface heterogeneity and derive the effective surface theory by dimensional reduction where bulk modes are integrated out. In Sec. III the Imry-Ma argument is used to estimate the domain size at which the influence of random pinnings becomes large. In Sec. IV the surface random positional pinning is treated within the Larkin, perturbative approximation, which allows us to compute exactly the short-scale correlation functions. In Sec. V we present a functional renormalization group analysis to treat fully nonlinear positional pinning necessary for characterization of long scale correlations. We demonstrate that, at finite $T$, this analysis predicts a 3D Cardy-Ostlund-like phase transition. Possible features of observation under polarized microscopy and x-ray scattering are analyzed in Sec. VI. In Sec. VII the importance of nonlinear elasticity is studied using a renormalization group method to show that it is less relevant, thereby justifying the validity of the harmonic elastic treatment, and the stability of the orientational order and relevant length scales are also discussed. In Sec. VIII we derive a theory for a surface disordered smectic cell with layers parallel to the substrates and show that it mimics a familiar bulk disordered $xy$ model in one lower dimension. We conclude in Sec. IX with a brief summary of the work and future directions. The technical details of our calculations are relegated to Appendices A-E.

We choose the coordinate system as illustrated in Fig. I so the smectic layers lie parallel to the $(x, z)$ plane, with the average layer normal and director $\hat{n}$ along the $z$ axis. The random substrate is located at $y = 0$ and running perpendicular to the $y$ axis.

Neglecting elastic nonlinearities we model a half-infinite bookshelf geometry smectic cell with a heterogeneous substrate by an energy functional

\[
H_{\text{bulk}} = \int \! d^{d-1}x \int_0^\infty \! dy \left[ \frac{K}{2} (\nabla_z^2 u)^2 + \frac{B}{2} (\partial_z u)^2 \right] + H_{\text{pin}},
\]

in which $u(x, y)$ is the distortion of smectic layer at position $r = (x, y)$ and in 3D $x = (x, z)$ spans the 2D random substrate and $y$ is the axis into the bulk of the cell.

B. Surface pinnings

The surface pinning energy of the substrate is given by

\[
H_{\text{pin}} = H_y + H_{dn} + H_{dp},
\]

including uniform pinning of the layers, coupling of the substrate with the directors $\hat{n}$ and smectic density $\rho(x)$ on the $y = 0$ substrate, respectively.

To stabilize the bookshelf cell geometry, a uniform component of the pinning is realized on the $y = 0$ substrate via

\[
H_y = \int \! d^{d-1}x \frac{W'}{2} (\hat{n} \cdot \hat{y})^2,
\]

which dictates the layers to be perpendicular to the substrate. In experiment, this is imposed by a uniform structureless treatment of the substrate.

Generically, the interaction between the substrate and the liquid crystal also includes the coupling between the nematic director $\hat{n}$ and the local random pinning axis, $g(x) = (g_x, g_y, g_z)$, as well as the coupling between the smectic density $\rho(x)$ and the local random scalar potential $U(x)$. These are determined by the substrate’s local chemical and physical structure (composition, roughness, rubbing, etc.). The nematic director $\hat{n}$ is pinned by the local random pinning axis $g(x)$, with

\[
H_{dn} = -\int \! d^{d-1}x [\hat{n} \cdot g(x)]^2.
\]

We approximated this weak pinning by specializing to the smectic state, with the layer normal $\hat{n}$ taken along $\hat{z} = \sqrt{T - \delta n^2} + \delta n$ and $\delta n \approx -\nabla_z u$. With this, $H_{dn}$ becomes

\[
H_{dn} \approx \int \! d^{d-1}x \left\{ \left[ g_x^2(x) - g_x^2(x) \right] (\partial_x u)^2 + \left[ g_y^2(x) - g_y^2(x) \right] (\partial_y u)^2 - 2g_x(x)g_y(x)(\partial_x u)(\partial_y u) + 2g_x(x)g_z(x)(\partial_x u) + 2g_y(x)g_z(x)(\partial_y u) \right\}.
\]
For a rubbed substrate used in the experiment\cite{30}, the alignment is highly anisotropic such that $|g_x| \gg |g_y|$ and pinning of layer normal along $\hat{z}$ is imposed. Combining with Eq.~(12) and averaging over microscopic scales, we find

$$H_u + H_{dn} \approx \int d^{d-1}x \left[ \frac{W}{2} (\partial_y u)^2 + \frac{W^2}{2} (\partial_x u)^2 - h(x)(\partial_x u) \right]$$

(15)

in which

$$W = W' + 2 \left[ g^2(x) - g^2_{\perp}(x) \right],$$

$$W_Q = 2 \left[ g^2(x) - g^2_{\perp}(x) \right],$$

$$h(x) = -2g_x(x)g_y(x).$$

(16)

For strong pinning $\frac{W}{2}(\partial_y u)^2$, the linear terms in $(\partial_y u)$ in Eq.~(14) can be neglected and $\partial_y u$ is taken to be 0. Determined by the local chemical and physical structure, $h(x)$ is expected to be short ranged, with variance

$$\langle h(x)h(x') \rangle = \Delta_f \delta^{a-d-1}(x - x'),$$

(17)

where $\Delta_f$ is the ensemble average and $\delta^{a-d-1}(x)$ is a $(d-1)$-dimensional short-ranged function set by the scale on the order of the molecular size $a$. The precise form of $\delta^{a-d-1}(x)$ has no qualitative effect on the long-scale (longer than its range) behavior which is our focus here, and the effectiveness of field description of the system already averages out details on scales shorter than $a$. Thus, it can be replaced by a $\delta$ function $\delta^{d-1}(x)$ without loss of generality.

Similarly, the local random scalar potential $U(x)$ is also expected to be short-ranged, and we thereby take it to be Gaussian characterized by variance

$$\langle U(x)U(x') \rangle = \Delta_U \delta^{a-d-1}(x - x') \approx \Delta_U \delta^{d-1}(x - x'),$$

(18)

with strength $\Delta_U$. As studied in the context of bulk disorder for smectics in, e.g., aerogel\cite{6,7}, it couples to the smectic density on the $y = 0$ substrate with $u_0(x) = u(x, y = 0)$ the surface layer displacement

$$\rho(x) = \rho_0 + \sum_{n=1}^{\infty} \rho_n e^{inz_0}$$

(19)

through

$$H_{dp} = -\int d^{d-1}x \rho(x)U(x) \approx -\int d^{d-1}x V[u_0(x), x].$$

(20)

We also take the random positional pinning potential $V[u_0(x), x]$ to be Gaussian with short-ranged variance

$$\langle V[u_0(x), x]V[u'_0(x'), x'] \rangle = \left[ \rho_0^2 + \sum_{n=1}^{\infty} \rho_n^2 \frac{1}{2} \Re \left( e^{inz_0} \right) \right] \times \Delta_U \delta^{d-1}(x - x').$$

(21)

in which the nonlinear variance function $R_v(u_0 - u'_0)$ is given by

$$R_v(u_0 - u'_0) = \Delta_U \left\{ \rho_0^2 + \sum_{n=1}^{\infty} \rho_n^2 \cos \{ nq_0 \{ u_0(x) - u_0(x') \} \} \right\},$$

(22)

with the first dominant term corresponding to $q_0$ as studied in Sec. V B.

Putting these terms together, the surface pinning energy is given by

$$H_{pin} \approx \int d^{d-1}x \left\{ \frac{W^2}{2} (\partial_x u)^2 - h(x)(\partial_x u) - V[u_0(x), x] \right\},$$

(23)

where we take the random fields $h(x)$ and $V[u_0(x), x]$ to be characterized by a Gaussian zero-mean distribution with variances given in Eqs. (17) and (21) and impose $\partial_y u = 0$ on the $y = 0$ substrate to satisfy the strong pinning in Eq. (15). More generally, the random surface torque $h$ may also be a function the layer distortion $u_0$, with a periodic variance $\Delta_f (u_0 - u'_0)$. However, as we will show in Sec. V B such a generalization is unnecessary at long scales.

### C. Effective surface model

Since the surface disorder is confined to the front substrate at $y = 0$, no nonlinearities (within harmonic elastic treatment) appear in the bulk ($y > 0$) of the smectic cell. Consequently, it is convenient to exactly eliminate the bulk degrees of freedom $u(x, y)$ in favor of the layer distortion field on the random substrate, $u_0(x) \equiv u(x, y = 0)$. This can be done via a constrained path-integral method by integrating out $u(x, y)$ with a constraint $u(x, y = 0) = u_0(x)$, thereby obtaining an effective $(d-1)$-dimensional Hamiltonian for $u_0(x)$\cite{31}. Equivalently (for $T = 0$ properties), we can eliminate $u(x, y)$ by solving the Euler-Lagrange equation

$$K \nabla^4_1 u - B \partial_x^2 u = f(x)\delta(y),$$

(24)

with $f(x)\delta(y)$ representing the boundary condition that imposes $u_0(x)$ on the substrate. To this end, we Fourier transform $u(x, y)$ over $(x, y)$, obtaining an algebraic equation for

$$u(q, q_y) = \int d^{d-1}x dy u(x, y) e^{-iqx - iq_yy},$$

(25)
whose solution after Fourier transform over $q_y$ becomes (as shown in Appendix A)

$$u(q, y) = u_0(q_x, q_z)e^{-\frac{y}{\lambda}}\sqrt{\frac{\lambda^2 q_y^4 + q_z^4 + \gamma_2 q_y^2}{\sqrt{\lambda^2 q_y^4 + q_z^4 - \lambda q_y^2}}}$$

$$\times \left[ \frac{\sqrt{\lambda^2 q_y^4 + q_z^4 + \gamma_2 q_y^2}}{\sqrt{\lambda^2 q_y^4 + q_z^4 - \lambda q_y^2}} \sin \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_y^4 + q_z^4 - \lambda q_y^2} \right) + \cos \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_y^4 + q_z^4 - \lambda q_y^2} \right) \right]$$

(26a)

$$\equiv u_0(q_x, q_z)\phi(q, y), \quad (26b)$$

where $\lambda = \sqrt{K/\gamma}$ is the length that, deep in the smectic phase, is comparable to the microscopic length $\alpha$ (determined by the layer thickness or molecular size) and we define a shape function $\phi(q, y)$ that characterizes the extension of surface-imposed distortions into the bulk ($y > 0$). In obtaining Eq. (26), for strong surface pinning ($W \rightarrow \infty$) in Eq. (15), we also impose a constraint $\partial_y u = 0$ at $y = 0$. More generally, the relative importance of the sine and cosine contributions depends on the system and the homogeneous transverse pinning strength $W$.

After substituting the above solution into (10) and integrating out the $y$ (bulk) degrees of freedom in a half-infinite system ($0 \leq y < \infty$), the energy functional simplifies to an effective surface energy,

$$H_{surface} = \int \frac{d^d-2 q_x dq_y}{(2\pi)^{d-1}} \frac{\Gamma_{q} + W_Q q_y^2}{2} \left| u_0(q_x, q_z) \right|^2$$

$$- \int d^{d-1} x \left[ h(x) \partial_y u_0 + V(u_0, x) \right], \quad (27)$$

confined to the random substrate at $y = 0$, with

$$\Gamma_q = B\sqrt{2\lambda}\sqrt{\lambda^2 q_y^4 + q_z^4 + \gamma_2 q_y^2 + \gamma q_y^2}. \quad (28)$$

The resulting effective surface Hamiltonian is convenient for studying the surface properties of the system, with the bulk properties obtained from Eq. (20). Equivalently, this result can be obtained by solving the Euler-Lagrange equation and specifying the boundary conditions, as in the nematic liquid crystal cell with surface disorder [11].

By comparing the induced surface elastic energy $\Gamma_q \sim K q_y^3$ ($q_y \ll \lambda q_y^2$) with surface pinning due to rubbing on the substrate, $W_Q q_y^2$, we obtain an important length scale

$$l_W = \frac{K}{W_Q}. \quad (29)$$

On longer scales, the surface rubbing dominates, and $\Gamma_q$ can be approximated by $\Gamma_q \sim B\sqrt{2\lambda} q_y^{3/2}$. In this regime the effective kernel is given by

$$\Gamma_q + W_Q q_y^2 \approx B\sqrt{2\lambda} q_y^{3/2} + W_Q q_y^2, \quad (30)$$

with an anisotropic “elasticity” for small $q_y$, which differs markedly from the bulk smectic elasticity and $\Gamma_q$ surface smectic elasticity without a rubbed substrate.

However, for a weak pinning $W_Q$ this scale can be much larger than the sample region and thus $W_Q$ can be neglected. For the remainder of the paper we will focus on this more interesting nonrubbed substrate limit.

### D. Replicated model

In treating random heterogeneous systems it is often convenient to work with an effective translationally invariant field theory. This is possible via the standard replica “trick” [32], at the expense of introducing $n$ replica fields (with the $n \rightarrow 0$ limit taken at the end of the calculation). The disorder-averaged free energy is given by

$$\mathcal{F} = -T \ln \mathcal{Z} = -T \lim_{n \to 0} \mathcal{Z}^{\frac{-1}{n}}, \quad (31)$$

where the effective translationally-invariant replicated Hamiltonian $H^{(r)}_{surface}[u_0^n]$ is given by

$$H^{(r)}_{surface} = \sum_{\alpha} \int \frac{d^{d-2} q_x dq_y}{(2\pi)^{d-1}} \frac{\Gamma_{q} + W_Q q_y^2}{2} \left| u_0^n(q_x, q_z) \right|^2$$

$$+ \frac{1}{4T} \sum_{\alpha, \beta} \int d^{d-2} x dz \Delta f \left| \partial_x \left[ u_0^n(q_x, z) - u_0^n(q_x, z) \right] \right|^2$$

$$- \frac{1}{2T} \sum_{\alpha, \beta} \int d^{d-2} x dz \Delta e \left[ u_0^n(q_x, z) - u_0^n(q_x, z) \right]. \quad (32)$$

The advantage of the dimensional reduction in Sec. III is that formally the problem becomes quite similar to the extensively studied bulk random pinning model [22, 24, 33] in one lower dimension but at the expense of a modified long-range elasticity encoded in $\Gamma_q$, Eq. (28). As we observe from the coarse-graining procedure, in general the random orientational pinning may also be field dependent, with $\Delta f[u_0^n(q_x, z) - u_0^n(q_x, z)]$ a generic periodic function. We therefore generalized to the form in (32).

### III. ESTIMATE OF THE FINITE SMECTIC DOMAIN SCALES

The qualitative features of the response of the smectic cell to a heterogeneous substrate can be understood through a generalization of the Imry-Ma argument [20] to the surface-pinning problems [9–11]. In this section, we estimate the characteristic length scales beyond which pinning energies become significant in disturbing smectic order.
A. Bulk Imry-Ma analysis

For an ordered region of $L_x \times L_z$ on the heterogeneous substrate the distortions decay into the bulk within a depth of $L_y \sim L_x$. Consequently, the elastic energy cost of such region scales as

$$E_c \sim L_x^{d-1} L_z \left[ K(a/L_x^2) + B(a/L_z^2) \right]. \quad (33)$$

The two elastic contributions balance for $L_y^2 \sim k T$, as an expression of a Virial theorem, justified in detail in in Sec. III B. With this anisotropic scaling the elastic energy reduces to

$$E_c \sim B \lambda^2 L_x^{d-3} \sim B \lambda^2 a^{(d+1)/2} L_x^{d-3}/2. \quad (34)$$

In such region, the interaction of the layers with the random positional pinning can lower the energy by a typical value

$$E_p \sim V_p \sqrt{N_p} \sim \Delta q^2 \sqrt{L_x^{d-2} L_z \xi_0 (d-1)/2} \sim \Delta q^2 \lambda^{d-2/4} L_x^{d/4}, \quad (35)$$

where $V_p$ is the typical random pinning strength with zero mean and variance $\Delta q \approx V_p^2/\xi_0 (\xi_0$ is the pinning correlation length) and $N_p$ is the number of surface pinning sites. Comparing between $E_c, E_p$ shows that for dimensions $d < 6$, arbitrary weak random positional pinning always dominates over the elastic energy on sufficiently long scales,

$$L_x > \xi_x \sim (B^2/\Delta q)^{1/(6-d)}, \quad (36)$$

and

$$L_z > \xi_z \sim (B^2/\Delta q)^{2/(6-d)}. \quad (37)$$

Thus, long-range smectic order is always destabilized on these long scales by an arbitrarily weak random positional pinning.

Similarly, the random orientational pinning can lower the energy through interaction with the layers by a typical amount,

$$E_f \sim V_h \sqrt{N_h} a/L_x \sim \Delta q^{1/2} L_x^{d-2/1} \sim \Delta q^{1/2} L_x^{d-2/4}. \quad (38)$$

Comparing $E_f$ and $E_c$, we find that arbitrarily weak random orientational pinning destroys long range smectic order for $d < 4$ on sufficiently long scales

$$L_x > \xi_x \sim (B^2/\Delta q)^{1/(4-d)}, \quad (39)$$

and

$$L_z > \xi_z \sim (B^2/\Delta q)^{2/(4-d)}. \quad (40)$$

Reassuringly, as we will see, these length scales, identified through the Imry-Ma argument, are consistent with the domain sizes given in Eqs. (31) (32), obtained through a detailed field theoretical calculation.

B. Surface Imry-Ma analysis

A complementary (but equivalent to bulk) way of estimating the surface-pinning and bulk ordering competition is by using the substrate model derived in Sec. III C. From the effective surface theory given in Eq. (27) (with the pinning of $W_Q$ neglected), for an ordered region of $L_x \times L_z$ on the heterogeneous surface, the elastic kernel $\Gamma_q$ scales according to

$$\Gamma_q \sim B \lambda^2 L_x^{d-3} \sim B \lambda^{1/2} L_x^{d-3/2}. \quad (41)$$

Therefore the elastic energy cost is given by

$$E_c \sim L_x^{d-2} L_z B \lambda^2 a^2 L_x^{d-3} \sim B \lambda^2 a^2 L_x^{d-3/2} \quad (42)$$

or in terms of $L_z$

$$E_c \sim L_z^{d-2} L_z B \lambda^2 a^2 L_z^{d-3/2} \sim B \lambda^2 a^2 L_z^{d-3/2}, \quad (43)$$

with the same scaling as Eqs. (33). Comparing with the scaling of the random pinning energies given in Eqs. (34) and (35), the Imry-Ma argument of effective surface Hamiltonian leads to the same critical dimension and characteristic lengths as in Sec. III A.

IV. SHORT SCALE “LARKIN” ANALYSIS: RANDOM FORCE APPROXIMATION

A. Random force (linear) approximation

The importance of surface pinning can be assessed by computing smectic layer distortions $u_0(x)$ at $y = 0$ surface (dominated by the zero-temperature distortions) within the Larkin approximation [19], which amounts to a linear random force approximation, $F(x) = \partial_u V[u_0(x), y] |_{y=0}$ to the random potential $V[u_0(x), y]$, with inherited Gaussian statistics and variance

$$F(x) F(x') = \Delta \delta^{d-1}(x-x') = -R_0''(0) \delta^{d-1}(x-x'). \quad (44)$$

In momentum space the pinning energy becomes

$$H_{pin} = \int \frac{d^{d-1} q_z}{(2\pi)^{d-1}} \left[ i q_z h(q_z, q_z) - F(q_z, q_z) \right] u_0(-q_z, -q_z). \quad (45)$$

Within this approximation, the correlation of the layer distortion on the random substrate ($y = 0$) is

$$C_{Larkin}(q) = \frac{T}{\Gamma_q} + \frac{\Delta q_z^2 + \Delta_x}{\Gamma_z^2}, \quad (46)$$

including the thermal contribution

$$C_{T, Larkin}(q) = \frac{T}{\Gamma_q}, \quad (47)$$

with $\Gamma_q$ given in Eqs. (33) (34) for the surface pinning by a random force.
and the contributions from both types of surface disorders,

$$C_{\Delta, \text{Larkin}}(q) = \frac{\Delta \Gamma \langle q^2 \rangle + \Delta_v}{\Gamma q^2}. \quad (48)$$

At long scales of interest, the contribution from thermal fluctuation is clearly subdominant to the zero temperature random pinning driven distortions. We therefore focus on this latter disorder dominant contribution.

1. Power counting

For various ranges of $q_x$ and $q_z$, the elastic kernel $\Gamma_q$ exhibits the following asymptotics

$$\Gamma_q \approx \begin{cases} B \sqrt{2} \lambda q_z^{3/2}, & \lambda q_z^2 \ll q_z, \\ B \sqrt{2} \lambda^2 q_z^3, & \lambda q_z^2 \gg q_z. \end{cases} \quad (49)$$

We note that there is a 2 : 1 ratio in the powers of $q_x$ and $q_z$ that reflects the anisotropy of the underlying smectic state. This anisotropic scaling is crucial in our estimates below the critical dimensions for the importance of surface pinning.

The correlation function contribution from random orientational pinning is given by

$$C_{\Delta, \text{Larkin}}(q) = \frac{\Delta \Gamma \langle q^2 \rangle^2}{\Gamma q^2} \approx \frac{\Delta \Gamma \langle q^2 \rangle^2}{(B \sqrt{2} \lambda q_z^{3/2} + B \sqrt{2} \lambda^2 q_z^3)^2}. \quad (50)$$

Thus, the scaling of smectic zero-temperature distortions is approximately given by

$$\langle u^2 \rangle \sim \Delta_f \int_{1/L_x} q_x^d d^{-2} q_x dq_x \sim L_x^{4-d}, \quad (51a)$$

$$\langle \tilde{u}^2 \rangle \sim \Delta_f \int_{1/L_x} q_x^d d^{-2} q_x dq_x \sim L_x^{4-d/2}, \quad (51b)$$

and leads to the lower critical dimension $d_{lc}^o = 4$ for the random orientational pinning.

For the random positional pinning, we have

$$C_{\Delta, \text{Larkin}}(q) = \frac{\Delta \Gamma \langle q^2 \rangle^2}{\Gamma q^2} \approx \frac{\Delta_v}{(B \sqrt{2} \lambda q_z^{3/2} + B \sqrt{2} \lambda^2 q_z^3)^2}, \quad (52)$$

which gives

$$\langle u^2 \rangle \sim \Delta_v \int_{1/L_x} q_x^d d^{-2} q_x dq_x \sim L_x^{6-d}, \quad (53a)$$

$$\langle \tilde{u}^2 \rangle \sim \Delta_v \int_{1/L_x} q_x^d d^{-2} q_x dq_x \sim L_x^{6-d/2}, \quad (53b)$$

leading to $d_{lc}^p = 6$ as the lower critical dimension for the positional pinning.

This agrees with our Imry-Ma analysis of the previous section and is to be contrasted with the bulk predictions of Ref. [7], which finds

$$\langle u^2 \rangle \sim \Delta_f \int_{q_x^d} q_x^d d^{-2} q_x dq_x \sim L_x^{5-d}, \quad (54a)$$

$$\langle \tilde{u}^2 \rangle \sim \Delta_v \int_{q_x^d} q_x^d d^{-2} q_x dq_x \sim L_x^{7-d}, \quad (54b)$$

with $d_{lc}^{\text{bulk}} = 5$ and 7 for for bulk orientational and positional random pinning, respectively. Thus, similarly to the surface disordered nematic cell discussed in Ref. [10] and [11], here, too, the restriction of the pinning to a surface reduces its lower critical dimensions down by one.

B. Domain size

The utility of the Larkin approximation is that it predicts the range of its own validity, limited to length scales where the distortion of $u_0$ is small. From Eqs. (57) and (59) it is clear that below the respective $d_{lc}$, the distortions diverge at long scales, signaling an instability of the smectic state and associated breakdown of Larkin approximation.

We identify the substrate extent $L_x$ and $L_z$ at which these smectic distortions grow large to the order of the layer spacing $a$ as (the so-called) Larkin domain lengths $\xi_x$ and $\xi_z$. More specifically, Larkin lengths are defined as

$$\langle u_0^2(x, z) \rangle = a^2, \quad (55)$$

which clearly depends on both surface orientational and positional disorder [22, 26, 35]. Thus, the values of $\xi_x, \xi_z$ depend on the relative strengths of these two types of disorder. For $L_x \ll \sqrt{L_z}$ in 3D, a simple analysis (with details relegated to Appendix B) gives

$$\langle u_0^2(x) \rangle \approx \int q_x^d \langle \Delta_f \rangle q_x^d \Gamma_q^2 \approx \frac{1}{3c} \frac{\Delta_v}{B^2 \lambda^3} L_z^2 + \frac{1}{c} \frac{\Delta_f}{B^2 \lambda^3} L_x, \quad (56)$$

with $c = \frac{4 \pi^2}{\pi^2} \approx 34.6$, leading to the equation for $\xi_x$

$$\frac{1}{3c} \frac{\Delta_v}{B^2 \lambda^3} \xi_x^3 + \frac{1}{c} \frac{\Delta_f}{B^2 \lambda^3} \xi_x \equiv a^2. \quad (57)$$

In the opposite limit of $L_z < L_x^2 / \lambda$ we instead get

$$\langle u_0^2(x) \rangle \approx \int q_x^d \langle \Delta_f \rangle q_x^d \Gamma_q^2 \approx \frac{1}{3c} \frac{\Delta_v}{B^2 \lambda^3} L_x^2 \frac{1}{2} + \frac{1}{c} \frac{\Delta_f}{B^2 \lambda^3} L_x \frac{1}{2}, \quad (58)$$

which leads to the equation for $\xi_x$,

$$\frac{1}{3c} \frac{\Delta_v}{B^2 \lambda^3} \xi_x^3 + \frac{1}{c} \frac{\Delta_f}{B^2 \lambda^3} \xi_x \equiv a^2. \quad (59)$$
As discussed in Appendix B, above equations are to be understood in the scaling sense and not as precise quantitative conditions.

The Larkin lengths $\xi_{x,z}$ in Eqs. (67) and (68) give the size of the smectic domains on the random substrate within which the elastic energy dominates over the pinning, which is effectively weak and Larkin approximation is valid.

More generally, in the presence of both types of pinning, the smectic domain size is determined by the minimum of $\xi_{x,z}^f$ and $\xi_{x,z}^v$, calculated in Appendix B

$$\xi_{x,z} = \xi_{x,z}^f(\xi_{x,z}^v, \xi_{x,z}) \approx \min\{\xi_{x,z}^f, \xi_{x,z}^v\},$$  \hspace{3cm} (60)

in which

$$\xi_{x,z}^f \approx \left[\frac{c B^2 \lambda_{x,z}}{2}\right]^2, \hspace{1cm} \xi_{x,z}^v \approx \sqrt{\lambda_{x,z}}^2,$$  \hspace{3cm} (61)

and

$$\xi_{x,z}^v \approx \left[\frac{3c B^2 \lambda_{x,z}}{2}x_{x,z}^2\right]^{2/3}, \hspace{1cm} \xi_{x,z}^v \approx \lambda_{x,z}^{1/3},$$  \hspace{3cm} (62)

The highly anisotropic domain constructed by $\xi_x$ and $\xi_z$ is illustrated in Fig. 1.

C. Surface correlation at short scales

As shown in Appendix C with Eq. (63) the $C(x, z)\approx C(0, z)$ can be easily calculated within the Larkin regime $x \ll \xi_x$ and $z \ll \xi_z$, and along the layer ($x$) and layer normal ($z$) direction, the orientational pinning contribution is given by

$$\left\{ \begin{array}{l} C_f(x,0) \approx \frac{\pi a^2 x/\xi_f^f} \sqrt{2\pi a^2 z/\xi_f^f} \approx \sqrt{2\pi a^2} \sqrt{z/\xi_f^f}, \\
C_f(0,z) \approx \frac{\pi a^2 z/\xi_f^v} \sqrt{2\pi a^2 z/\xi_f^v} \approx \sqrt{2\pi a^2} \sqrt{\lambda_{x,z}/\xi_f^f}, \\
\end{array} \right. \hspace{3cm} (63)$$

where $\xi_{f,x}$ are given in Eq. (61). At short scales $x \ll \xi_x$ and $z \ll \xi_z$, the behaviors of these correlation functions are plotted in Fig. 3. The contribution from random positional pinning is

$$\left\{ \begin{array}{l} C_v(x,0) \approx \frac{3a^2 \xi_x^2}{\xi_{v,x}^2}, \\
C_v(0,z) \approx \sqrt{8\pi a^2} \left(\frac{z}{\xi_z^v}\right)^{3/2}, \\
\end{array} \right. \hspace{3cm} (64)$$

in which $\xi_{v,x}^v$ are given in Eq. (62). At short scales, $x \ll \xi_x$ and $z \ll \xi_z$, these correlation functions are plotted in Fig. 3

Thus, within finite smectic domains $(x,z) \ll \xi_{x,z}$, on the random substrate we predict anisotropic power law correlations given above.

D. Estimate of distortions into the bulk

The nature of the distortions in the bulk of the cell, $y > 0$, can be deduced from the $u(q,y)$ in (20) and the distortions $u(0,q)$ on the heterogeneous surface computed above. The main feature of the $u(q,y)$ is that the amplitude of distortions at wavevector $q = (q_x, q_z)$ exponentially decays into the bulk with length

$$\xi_{q_{x,z}} \approx 1/D(q) \approx \left(\frac{2\lambda}{\sqrt{\lambda^2 q_x^2 + q_z^2 + \lambda q_z^2}}\right)^{1/2},$$  \hspace{3cm} (65)$$

where $D(q) = \frac{1}{\sqrt{2\pi}} \sqrt{\lambda^2 q_x^2 + q_z^2 + \lambda q_z^2}$. For surface smectic order limited by domain size $(\xi_x, \xi_z)$ the characteristic substrate surface wavevector $q_L$ is set by $(\xi_{x,z}^{-1}, \xi_{z}^{-1})$ and leads to

$$\xi_{y} \approx \left[D(\xi_{x,z}^{-1}, \xi_{z}^{-1})\right]^{-1} = \left(\frac{2\lambda}{\sqrt{\lambda^2 \xi_x^{-2} + \xi_z^{-2} + \lambda \xi_x^{-2}}}\right)^{1/2} \approx \xi_{x},$$  \hspace{3cm} (66)$$

in which $\xi_{x} \approx \sqrt{\lambda \xi_x}$ is used. Thus we predict that for $y > \xi_y$ (ignoring the more subtle distortions on scales
beyond the Larkin scale, see Sec. V, the smectic surface distortion will anneal away into the bulk. This allows us to define a $y$-dependent smectic domain size via a Larkin criterion on

$$
\langle u^2(y) \rangle = \int \frac{\Delta f q^2}{2} \left( |\phi(q,y)|^2 \right) \frac{dq_x dq_z}{(2\pi)^2}
\sim \int \frac{\Delta f q^2}{2} \left( |u_0(q)|^2 \right) \frac{dq_x dq_z}{(2\pi)^2}
\sim a^2 \xi_x(y)^{-2D} |\xi_x^{-1}(y)\xi_x^{-1}(y)| y,
$$

where we assume dominant orientational pinning (positional pinning can be similarly analyzed).

As usual, $\xi_x(y)$ is set by $\langle u^2(y) \rangle \simeq a^2$; thus, we have

$$
\xi_x(y) \approx \xi_x e^{2y/\xi_x(y)},
$$

A self-consistent solution for this equation is simply

$$
\xi_x(y) \approx \max (\xi_x, 2y),
$$

showing near healing of smectic order (but see Sec. V) at a distance $\xi_x$ into the bulk.

V. PHYSICS ON SCALES BEYOND SMECTIC DOMAINS

On length scales longer than the crossover scales $\xi_x, z$, the distortions of $u_0$ grow into a nonlinear regime, where the random-force (Larkin) approximation is inadequate, and the effects of the surface disorders must be treated nonperturbatively. As with bulk disorder problems, this can be done systematically using an FRG analysis [22–24].

A. Renormalization group analysis

We employ the standard momentum-shell RG transformation [24] by separating the layer distortion field into long- and short-scale contributions according to $u_0^\alpha(x, z) = u_0^\alpha(x, z) + u_0^\alpha(x, z)$ and perturbatively in the surface disorder integrate out the high wave-vector fields $u_0^\alpha(x, z)$ that take support in an infinitesimal shell $\Lambda/b < q_x < \Lambda \equiv 1/a$, with $b = e^{\delta t}$. We follow this with a rescaling of lengths and of the long wavelength part of the field in real space,

$$
x = bx', \quad (70)
\quad z = b^w z', \quad (71)
\text{and in momentum space,}
$$

$$
q_x = b^{-1} q_x', \quad (73)
\quad q_z = b^{-w} q_z', \quad (74)
\text{to restore the UV cutoff back to } \Lambda = 1/a. \text{ Because a smectic liquid crystal is periodic under translations by a multiple of the layer spacing, it is convenient to choose the arbitrary field dimension } \phi = 0 \text{ and take } w = 2 \text{ so the associated smectic period and length } \lambda = \sqrt{K/B} \text{ are not rescaled under the RG transformation.}
$$

For simplicity and clarity of presentation we focus on an infinitely thick cell with the Hamiltonian given in Eq. (82), where both disorder strengths are general functions of $u_0(x, z)$, and employ the functional renormalization group method. The above rescaling leads to zeroth order RG flows of the effective couplings, which for a thick cell are given by

$$
\gamma'_q(\lambda) = b^d \gamma_q, \quad (76)
\quad B'(\lambda) = b^{d-3} B, \quad (77)
\quad \Delta f'(u, \lambda) = b^{d-2} \Delta f(u), \quad (78)
\quad R'_u(\lambda) = b^d R_u(u), \quad (79)
$$

where $T$ is kept fixed and $\Delta f(u)$ is a periodic function of the field $u$.

The Hamiltonian can be separated into three parts,

$$
H^{(r)}_{\text{surface}} = H_0 + H_{\Delta f} + H_{\Delta x}, \quad (80)
$$

FIG. 4. (Color online) The correlation function on the heterogeneous substrate along and perpendicular to smectic layers, with dominant positional pinning, valid only inside Larkin domains, $(x, z) < \xi_x, z$. On longer scales an RG analysis is necessary.
where \( H_{\Delta_f} \) and \( H_{\Delta_v} \) are given by

\[
H_{\Delta_f} = \frac{1}{4T} \sum_{\alpha, \beta} \int d^{d-2} x d z \Delta_f \left[ u_0^\alpha(x, z) - u_0^\beta(x, z) \right] \times \left[ \partial_x \left[ u_0^\alpha(x, z) - u_0^\beta(x, z) \right] \right]^2 ,
\]

\[
H_{\Delta_v} = -\frac{1}{2T} \sum_{\alpha, \beta} \int d^{d-2} x d z R_v \left[ u_0^\alpha(x, z) - u_0^\beta(x, z) \right] ,
\]

and \( H_0 \) has already been given by the elastic term in Eq. (82).

We limit the FRG analysis to one-loop order, performing the momentum shell integration over the high-wave-vector components \( u_0^\alpha \), perturbatively in the nonlinearities \( \Delta_f \left[ u_0^\alpha(x, z) - u_0^\beta(x, z) \right] \) and \( \Delta_v \left[ u_0^\alpha(x, z) - u_0^\beta(x, z) \right] \). The change in the Hamiltonian due to this coarse-graining is given by

\[
\delta H_s^{(r)} = \langle H_{\Delta_f} \rangle + \langle H_{\Delta_v} \rangle - \frac{1}{2T} \langle H_{\Delta_f}^2 \rangle - \frac{1}{2T} \langle H_{\Delta_v}^2 \rangle + \ldots . \tag{83}
\]

Relegating the detailed calculations to Appendix [D], this coarse-graining procedure leads to functional RG flow equations for \( \Delta_f(u) \) and \( R_v(u) \)

\[
\partial_t \Delta_f(u, \ell) = (d - 2) \Delta_f(u) + \eta \Delta_f''(u) - \frac{A}{2e^2} R_v''(u) R_v''(u) - A_4 \Delta_f(u) \Delta_f''(u) \\
- A_5 \left[ \Delta_f(u) \Delta_f''(u) - \Delta_f(u) \Delta_f''(0) - \Delta_f(0) \Delta_f''(u) \right] - A_6 \left[ \frac{1}{2} \Delta_f(u) \Delta_f''(u) - \Delta_f(u) \Delta_f''(0) \right] \\
+A \left[ \Delta_f''(u) R_v''(u) - \Delta_f''(0) R_v''(u) - \Delta_f''(u) R_v''(u) \right] ,
\]

\[
\partial_t R_v(u) = d R_v(u) - \zeta \Delta_f(u) + \eta R_v''(u) + A \left[ \frac{1}{2} R_v''(u) R_v''(u) - R_v''(u) R_v''(0) \right] + A_3 \left[ \frac{1}{2} \Delta_f(u) \Delta_f(u) \\
- \Delta_f(u) \Delta_f(0) \right] - A_5 \left[ \Delta_f(u) R_v''(u) - \Delta_f(0) R_v''(u) - \Delta_f(u) R_v''(0) \right] ,
\]

in which \( \eta = \frac{T}{2 B \pi \lambda} \), \( A = \frac{\pi^2}{B \lambda^3} \), and other coefficients are nonuniversal constants given in Appendix [D].

B. Single harmonic form of positional pinning

In general, the fully nonlinear functions \( \Delta_f(u) \) and \( R_v(u) \) in Eq. (82) need to be treated under the functional renormalization group coarse graining \([7, 22, 24]\). However, at finite temperature and in 3D, it is clear from Eqs. (81) and (82) that, at long scales, the pinning is dominated by the field-independent \( \Delta_f \) and the lowest harmonic of the positional disorder \([5]\),

\[
R_v(u) = \Delta_v \cos \left( \frac{q_0 u}{\sqrt{2}} \right) , \tag{86}
\]

where \( q_0 = 2\pi/a \) is the smectic wave number. Because, at finite \( T \), \( \eta \) is nonzero, all higher, \( n > 1 \) harmonics of \( R_v(u) \) in Eq. (22) are less relevant with eigenvalues \( \lambda_n = 3 - \eta n^2 q_0^2 \), \( \lambda_1 \) and, thus, can be neglected.

With these considerable simplifications, the flow of the surface disorder strengths in Eqs. (81) and (82) reduce to

\[
\partial_t \Delta_f = \Delta_f + \frac{A}{4 \lambda^2} \eta q_0^2 \Delta_f^2 ,
\]

\[
\partial_t \Delta_v = (3 - \eta q_0^2) \Delta_v - A \eta q_0^2 \Delta_v^2 , \tag{88}
\]

The dimensionless coupling of the random positional pinning, \( \Delta_v = A \eta q_0 \Delta_v = 6 \pi^2 (a/\xi_v^3) \), which is dimensionless measure of the random positional pinning, flows according to

\[
\partial_t \Delta_v = \left( 3 - \frac{T \eta q_0^2}{2 \pi B \lambda} \right) \Delta_v - \Delta_v^2 . \tag{89}
\]

Taking an ansatz \( \hat{\Delta}_v(\ell) = f(\ell) e^{(3 - \frac{T \eta q_0^2}{2 \pi B \lambda}) \ell} \), the solution to this flow equation can be readily obtained:

\[
\hat{\Delta}_v(\ell) = \frac{\left( 3 - \frac{T \eta q_0^2}{2 \pi B \lambda} \right) \hat{\Delta}_v(0) e^{(3 - \frac{T \eta q_0^2}{2 \pi B \lambda}) \ell}}{\left( 3 - \frac{T \eta q_0^2}{2 \pi B \lambda} \right) + \hat{\Delta}_v(0) e^{(3 - \frac{T \eta q_0^2}{2 \pi B \lambda}) \ell} - 1} . \tag{90}
\]

Thus we find that \( \hat{\Delta}_v \) decays to the \( \hat{\Delta}_v^* = 0 \) fixed line for \( T > 6 \pi B \lambda / q_0^2 \approx T_g \), and flows to fixed line

\[
\hat{\Delta}_v^* = \left( 3 - \frac{T \eta q_0^2}{2 \pi B \lambda} \right) \tag{91}
\]

for \( T < T_g \), as illustrated in Fig. 8.

We therefore predict that a 3D surface disordered smectic cell exhibits a Cardy-Ostlund-like [27] phase transition at \( T_g = 6 \pi B \lambda / q_0^2 \), between a high temperature thermal smectic phase, in which, at long scales, the surface positional pinning is averaged away by thermal fluctuations and a low-temperature random-pinned smectic glass phase controlled by the nontrivial \( \Delta_v^*(T) \) fixed line. This surface pinned state (and the associated transition) is quite similar to the super-rough phase of
From this equation, we learn that even if the bare value \( \ell \) is zero, under coarse graining, at long scales the random-field pinning, \( \Delta_v \), generates a nonzero random orientational pinning \( \Delta_f(\ell) \). Since for \( T > T_g \), \( \Delta_v \to 0 \), the flow of \( \Delta_f \) reduces to \( \partial_\ell \Delta_f = \Delta_f \), with a trivial solution \( \Delta_f(\ell) = \Delta_f \). It is clear that the random orientational pinning is strongly relevant even in the high temperature phase, \( T > T_g \), with the latter distinguished by the irrelevance of the positional pinning, \( \Delta_v \to 0 \).

In contrast, in the low-temperature phase, \( T < T_g \), the dimensionless strength of surface positional disorder approaches a nonzero value, \( \Delta_v \to \Delta_v^* > 0 \). Replacing \( \Delta_v \) in Eq. (92) by its fixed point value, we obtain

\[
\Delta_f(\ell) = \left[ \Delta_f + \pi^2(\Delta_v^*)^2 \right] e^\ell - \pi^2(\Delta_v^*)^2.
\]

Similarly to the bulk disorder result \[11\], as \( \ell \to \infty \), this has the same asymptotic behavior as in the high-temperature phase, \( \Delta_f(0) \), but with the enhanced nonuniversal amplitude \( \Delta_f \) acquiring an additional contribution that scales with \( (T_g - T)^2 \) for \( T < T_g \).

C. Matching analysis

As discussed earlier, correlation function on scales shorter than the Larkin domain size can be computed within the random-force approximation in Sec. [IV]. However, at scales longer than the domain size, effective pinning grows large (compared to the elastic energy) and can, therefore, no longer be treated perturbatively within the random force model. Nevertheless, we can utilize the RG and matching method to effectively overcome this difficulty. It allows us to establish a relation between a correlation function at long scales (beyond the domain size), which is impossible to calculate directly due to the aforementioned infrared divergences, to this correlation function at short scales (below the domain size), which can be easily calculated in a controlled perturbation theory \[7, 11, 22, 41, 42, 43\] of Sec. [IV].

For \( T < T_g \), the surface positional disorder is relevant. However, near the Cardy-Ostlund transition \( T_g \), \((3 - \eta Br^2) \ll 1 \), and the fixed point value of dimensionless positional pinning is small \( (\Delta_v^* \ll 1) \). Making use of the matching method, we establish a relation between replicated correlation functions at short and long scales:

\[
C_{\alpha\beta} [q_x, q_z; \Gamma_q(0), \Delta_f(0), \Delta_v(0)]
\]

\[
\equiv \frac{\langle u_0^\alpha(q_x, q_z) u_0^\beta(q_x', q_z') \rangle}{\delta^2(q + q')}
\]

\[
= e^{(1+\omega)\ell} C_{\alpha\beta} \left[ e^\ell \omega^\ell q_x, q_z; \Gamma_q(\ell), \Delta_f(\ell), \Delta_v(\ell) \right].
\]

We then choose the value of \( \ell = \ln (\Lambda/\eta Br^2) \), so the rescaled momentum \( q_x \) is at the cutoff \( \Lambda \) and therefore the correlation function on the right-hand side of the above equation can be safely evaluated perturbatively. This gives

\[
C_{\alpha\beta} [q_x, q_z; \Gamma_q(0), \Delta_f(0), \Delta_v(0)]
\]

\[
= \left( \frac{\Lambda}{\eta Br^2} \right)^{1+\omega} C_{\alpha\beta} \left[ \Lambda, (\Lambda/\eta Br^2)^\omega q_z; \Gamma_q^*(\ell^*), \Delta_f(\ell^*), \Delta_v(\ell^*) \right],
\]

and for \( \ell \to \infty \) corresponds to long scales with \( q_x \to 0 \), where \( \ell^* \) is big enough so the disorder strengths on the right-hand side can be replaced by their fixed values.

Safely calculating the correlation function at the cutoff scale on the right-hand side using the Larkin analysis of Sec. [IV] we obtain

\[
C_{\alpha\beta} \left[ \Lambda, (\Lambda/\eta Br^2)^\omega q_z; \Gamma_q^*(\ell^*), \Delta_f(\ell^*), \Delta_v(\ell^*) \right]
\]

\[
= \frac{T \delta_{\alpha\beta} + \Delta_f(\ell^*) \Lambda^2 + \Delta_v(\ell^*)}{\Gamma_q^2(\ell^*)},
\]

where the \( \ell^* \) dependent parameters the recursion rela-
enough and, therefore, \( \ell^* = \ln (A/q_x) \):

\[
\Gamma_{q}(\ell^*) = \left( \frac{A}{q_x} \right)^3 \Gamma_{q},
\]

\[
\Delta_f(\ell^*) = \frac{\hat{\Delta}_f(\ell^*)}{A(\ell^*)q_0^2} = \frac{\Lambda}{q_x} \left[ \Delta_f + \frac{\pi^2}{A q_0^2} \left( \hat{\Delta}_v^* \right)^2 \right],
\]

\[
\Delta_v(\ell^*) = \frac{\hat{\Delta}_v(\ell^*)}{A(\ell^*)q_0^2} = \frac{\hat{\Delta}_v^*}{A q_0^2}.
\]

Here \( A(\ell) = A \) is a constant given by Eq. (113). In the last two equations we have taken \( q_x \) to be small enough and, therefore, \( \ell^* \) large enough so the \( \hat{\Delta}_v(\ell^*) \) has flowed to its fixed point value given in Sec. VI B and the low-temperature solution of \( \hat{\Delta}_f(\ell) \) is used, with \( \ell^* \) large enough that the second term in Eq. (102) can be ignored.

Combining these ingredients, we therefore find

\[
C_{\alpha\beta} [q_x, q_z; \Gamma_{q}, \Delta_f, \Delta_v]
= \frac{T \delta_{\alpha\beta}}{\Gamma_{q}} \frac{\Delta_f}{\Gamma_{q}^2}
\left[ 1 + \frac{\xi_f}{8 \pi^2 a} \left( \hat{\Delta}_v^* \right)^2 \right],
\]

in which \( \Gamma_{q} \) is the bare long-range surface elasticity kernel given in (28), \( \Delta_f \) is the bare strength of orientational disorder strength, and \( \hat{\Delta}_v^* \) is the fixed value given in (31). It is easy to see that the \( \frac{\xi_f}{8 \pi^2 a} \hat{\Delta}_v^* \) term arising from the random positional pinning is negligible as \( q_x \to 0 \) compared with the contribution of the surface orientational pinning. Thus, the smectic phonon correlation functions in the high- and low-temperature phases are only subtly distinguished by the enhanced amplitude of surface orientational pinning from \( \Delta_f \) to

\[
\Delta_f(T) = \Delta_f \left[ 1 + \frac{\xi_f}{8 \pi^2 a} \left( \hat{\Delta}_v^* \right)^2 \right].
\]

The above matching calculation gives the long-scale momentum-space surface correlation function

\[
C(q) = \frac{\Delta_f \delta_f(T) q_0^2}{\Delta_f},
\]

in which \( \delta_f(T) = \Delta_f(T)/\Delta_f \), as given in Eq. (6), distinguishes the high- \( (T > T_g) \) and low- \( (T < T_g) \) temperature phases.

Moreover, the correction to the orientational disorder at long scales, \( \Delta_f(T) - \Delta_f \), that we approximated in Eq. (12) by the fixed point value of the positional disorder which is zero for \( T > T_g \) and quadratic in \( (T_g - T) \) for \( T < T_g \), is quantitatively inaccurate. The exact solution of the flow equation for \( \Delta_f \) given in Eq. (12) with \( \Delta_v(\ell) \) in (90) leads to a long scale correction of \( \Delta_f \) in the correlation function that depends on the “bare” value of \( \Delta_v \), and is non-zero for \( T > T_g \), as shown in Fig. 3. This difference does not change the qualitative behavior of the system, e.g., the experimental feature of the x-ray scattering peaks described in Sec. VI B. However, it may be important for quantitative comparison with experiments.

D. Surface correlation function at long scales

\[
\frac{f(0)}{\pi (\pi - 2)}
\]

FIG. 6. (Color online) The exact correction to the long-scale dimensionless strength of the orientational pinning as a function of temperature, obtained by numerically integrating Eqs. (10) and (12) for different “bare” values of the positional disorder: \( \hat{\Delta}_v = 0.1 \) and \( \hat{\Delta}_v = 0.2 \). As a comparison, the dashed curve is the approximation based on the fixed point value of \( \hat{\Delta}_v \) used in Eqs. (8), (9) and (93).

As discussed in Appendix B, the full behavior of the real-space long scale correlations can be summarized as

\[
C(x, z) = \frac{\Delta_f(T)}{4 \pi^2 B^2 \lambda^3} h f(t),
\]

in which \( t = \frac{x}{2 \lambda} \) and \( f(t) \) (plotted in Fig. 7) is given by

\[
f(t) = \pi (\pi - 2) + \pi \left[ 2 + 2e^{-\sqrt{\pi t}} - \pi \text{erfc} \left( \frac{1}{2 \sqrt{t}} \right) \right]
+ \frac{\sqrt{2}}{3 \sqrt{t}} \left[ 3 \Gamma \left( \frac{3}{4} \right) \Gamma \left( \frac{3}{4} \right) _1 F_2 \left( \frac{1}{4}, \frac{1}{4}, \frac{3}{4}; \frac{1}{64 t^2} \right) \right]
- \Gamma \left( \frac{1}{4} \right) \Gamma \left( \frac{5}{4} \right) _1 F_2 \left( \frac{3}{4}, \frac{3}{4}, \frac{1}{4}; \frac{1}{64 t^2} \right),
\]

where \( _1 F_2(a_1; b_1, b_2; x) \) is the generalized hypergeometric function.
function. The limiting behavior of \( f(t) \) is given by
\[
f(t) \approx \begin{cases} \pi(\pi - 2) - 4\pi t^2, & \text{for } t \ll 1, \\ 2.64\sqrt{t}, & \text{for } t \gg 1. \end{cases}
\] (105)

In the \((x, z)\) plane, the above limits correspond to regions near the \(x\) and \(z\) axes, where simple asymptotic form of the correlation function \( C(x, z) \) is available, as shown in Fig. 8. In real space along \(x\), it is given by
\[
C(x, 0) \approx 2\frac{(\pi - 2)\Delta f(T) \pi x}{4\pi^2 B^2 \lambda^3} = \frac{\pi a^2 \delta_f(T)x}{\xi_x^f} = \frac{\pi a^2 x}{\xi_x(T)},
\] (106)
where \( \xi_x(T) = \xi_x^f/\delta_f(T) \). Along \(z\) we instead find
\[
C(0, z) \approx 2a^2 \delta_f(T) \sqrt{\frac{\pi}{2}} \frac{|z|}{\xi_z(T)} = \sqrt{2\pi a^2} \sqrt{z/\xi_z(T)},
\] (107)
where \( \xi_z(T) = \xi_z^f/\delta_f(T) \). Thus at long scales the correlation function asymptotically scales identically to that in the Larkin’s perturbative regime, \( \xi^2 \), but with an amplitude enhanced below \( T_s\), as illustrated in Fig. 8.

Within the harmonic elastic theory (i.e., neglecting elastic nonlinearities and dislocations) we expect the above predictions to be asymptotically exact. We explore the role of elastic nonlinearities in Sec. VII A where we show that they indeed are expected to modify our predictions on scales longer than the nonlinear length scale \( \xi_{NL} \) but leave the challenging problem of their study to future research.

VI. EXPERIMENTAL PREDICTIONS

We next explore the experimental signatures of our predictions for the surface pinned smectic cell, focusing on polarized light microscopy and x-ray scattering.

FIG. 8. (Color online) The long-scale surface phonon correlation function \( C(x, z) \), exhibiting limiting behavior \( C(x, z) \sim x \) and \( \sqrt{z} \) for small and large values of \( t = \lambda z/x^2 \), respectively.

FIG. 9. (Color online) The two-point smectic phonon correlation function along \( x \) and \( z \) axes on the random substrate at \( y = 0 \). For temperature \( T > T_s \) the correlation is the same as the short-scale result, \( \xi^2 \), while below \( T_s \) it is modified by the enhanced amplitude \( \delta_f(T) \), \( \xi^2 \) and \( \xi^2 \).

A. Cross-polarized light microscopy

In smectic cells with weak random substrate pinning, the molecular orientation is expected to vary slowly in the bulk, and under standard conditions we expect the Mauguin limit be valid with polarization of light following local optic axis. Under such conditions, a convenient geometry to probe the substrate-driven smectic distortion is that of a crossed polarizer-analyzer pair, with the polarizer aligned with a well rubbed back substrate. In this geometry, the transmission vanishes in the absence of smectic distortions. Thus, transmitted light directly images the optic axis distortions on the front heterogeneous substrate \( \xi^2 \). This provides a sensitive way to investigate statistics of the surface smectic layer distortions \( \partial_z u_0(x, z) \) in a smectic cell weakly pinned by a dirty substrate.

Here, we only consider smectic order distortions on the short scales (within the Larkin regime) of thick smectic cells where the effects are most pronounced. The subtle long scale asymptotic behavior predicted here is unlikely to be accessible in current experiments, as it requires currently unavailable detailed quantitative analysis. Short-scale treatment below can also be readily generalized to long scales. We take the back substrate to be rubbed and, therefore, with the optic (nematic) axis well aligned along the \( z \) axis, while near the
front \( y = 0 \) substrate the smectic order is subject to random orientational and positional pinning of the dirty substrate.

As alluded to above, in this weakly pinned Mauguin limit optical transmission is determined by the azimuthal distortions of the optic axis (layer normal) orientation \( \phi_0(x, z) = \phi(x, y, z)|_{y=0} \) on the random substrate. In this geometry with the polarizer at the back substrate along the \( z \) axis, and analyzer at the front substrate along the \( x \) axis, the transmitted optical field is given by

\[
E_{\text{out}}(x, z) = E_{\text{in}} \sin \phi_0(x, z) \approx -E_{\text{in}} \frac{\partial u_0(x, z)}{\partial x}. \tag{108}
\]

This gives the polarized light microscopy intensity,

\[
I_{\text{out}}(x, z) \approx I_{\text{in}} |\partial_x u_0(x, z)|^2. \tag{109}
\]

Thus, the average transmitted intensity is proportional to the variance of the smectic layer normal fluctuations on the heterogeneous substrate,

\[
\frac{T_{\text{out}}}{I_{\text{in}}} \approx |\partial_x u_0(x, z)|^2. \tag{110}
\]

From the local intensity we can also obtain a correlation function of the transmitted intensity, related to spatial smectic phonon correlations:

\[
C^I(x - x', z - z') = \frac{I_{\text{out}}(x, z) I_{\text{out}}(x', z')}{I_{\text{out}}^2} \approx \frac{I_{\text{in}}^2 |\partial_x u_0(x, z)|^2 |\partial_x u_0(x', z')|^2}{|\partial_x u_0(x, z)|^2}.
\]

\[
\approx T_{\text{out}}^2 \left( 1 + 2 \left[ \frac{\partial_x u_0(x, z) \partial_x u_0(x', z')}{|\partial_x u_0(x, z)|^2} \right]^2 \right), \tag{111}
\]

where we utilized Gaussian approximation valid at short scales.

1. **Surface random orientational pinning**

For a dirty substrate where the orientational pinning dominates over positional disorder, the transmitted intensity averaged over the Larkin domain can be straightforwardly calculated and is given by

\[
\frac{T_{\text{out}}}{I_{\text{in}}} = \frac{|\partial_x u_0(x, z)|^2}{|\partial_x u_0(x, z)|^2} \approx \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \int_1^{1/\xi_x} \frac{dq_x}{q_x^2} \approx \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \xi_x. \tag{112}
\]

In the regime of dominant orientational disorder, the transmission intensity-intensity correlation function along the \( x \) axis, \( C^I(x, 0) \) can be straightforwardly computed by noticing that

\[
\frac{\partial_x u_0(x + x', z) \partial_x u_0(x', z)}{|\partial_x u_0(x, z)|^2} = \sin \left( \frac{x}{a} \right) \frac{1}{x/a}. \tag{113}
\]

and thus we find

\[
C^I(x, 0) = T_{\text{out}}^2 \left[ 1 + 2 \left( \frac{\sin \left( \frac{x}{a} \right)}{\sqrt{\frac{2a}{\pi}}} \right)^2 \right]. \tag{114}
\]

Similarly, the light intensity-intensity correlation along the \( z \) axis is given by

\[
C^I(0, z) = T_{\text{out}}^2 \left[ 1 + 2 \left( \frac{\pi a}{2z} C_F \left( \sqrt{\frac{2z}{\pi a}} \right) \right)^2 \right], \tag{115}
\]

where \( C_F(z) = \int_0^z \cos (\pi t^2/2) dt \) is the Fresnel integral.

These correlation functions probe surface orientational order, that for weak pinning is long range ordered, with structure only on the scale of the layer spacing \( a \).

2. **Surface random positional pinning**

For cells dominated by positional pinning the average transmission intensity is given by

\[
\frac{T_{\text{out}}}{I_{\text{in}}} = \int_0^{\Delta} d\xi \int_0^{\Delta} dq_x \frac{\partial_x u_0(x, z)}{|\partial_x u_0(x, z)|^2} \approx \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \int_1^{1/\xi_x} \frac{dq_x}{q_x^2} \approx \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \xi_x. \tag{116}
\]

where we cutoff the average by the smectic domain size, \( \xi_x \approx \xi_x^v \), given in Eq. (52).

The intensity-intensity correlation function along the \( x \) axis calculated from (111) is given by:

\[
C^I(x, 0) \approx T_{\text{out}}^2 \left( 1 + 2 \left[ \frac{1}{\xi_x} \int_1^{1/\xi_x} \frac{1}{q_x^2} \cos (q_x x) dq_x \right] \right) \approx T_{\text{out}}^2 \left( 1 + 2 \left( 1 - \frac{\pi x}{2 \xi_x} \right)^2 \right), \tag{117}
\]

where we have extended the upper bound of integral to infinity,

\[
\int_1^{1/\xi_x} \frac{1}{q_x^2} \cos (q_x x) dq_x \approx - \frac{\pi x}{2 \xi_x} \cos \left( \frac{x}{\xi_x} \right) + \frac{x}{\xi_x} \sin \left( \frac{x}{\xi_x} \right) \approx 1 - \frac{\pi x}{2 \xi_x}, \tag{118}
\]
valid for \(0 < a \ll x \ll \xi_z\) and where \(\text{Si}(z) = \int_0^z \frac{\sin(t)}{t} \, dt\) is the sine integral function.

Similarly, at constant \(x\) along the layer normal, the intensity correlation function is given by

\[
C^I(0, z) = \mathcal{T}^I_{\text{out}} \left\{ 1 + 2 \left[ \frac{1}{2} \frac{\pi}{\sqrt{2\xi_z}} \int_1^{1/a} \cos \left( \frac{q_z z}{q_z^2} \right) \, dq_z \right]^2 \right\}
\]

\[
\approx \mathcal{T}^I_{\text{out}} \left\{ 1 + 2 \left( 1 - \frac{\pi z}{2\xi_z} \right)^2 \right\}
\]

\[
= \mathcal{T}^I_{\text{out}} \left( 3 - 4 \frac{\pi z}{2\xi_z} + \frac{\pi z^2}{\xi_z^2} \right),
\]  \tag{119}

valid for \(0 < a \ll z \ll \xi_z\). The intensity-intensity correlations decay to their asymptotic (transmission) value on the scale of smectic domains \(\xi_{xz}\).

In fact, we expect the intensity-intensity correlations predicted by Eqs. (114), (115), (117) and (119) to be observable in crossed polarized light microscopy on a thick smectic cell with a single dirty substrate.

### B. X-ray scattering and characteristic lengths

Experimental studies of a smectic cell \cite{17,18} observed that the smectic x-ray scattering peak broadens significantly as temperature lowers towards the A-C transition. In this section, we analyze the x-ray scattering utilizing the smectic cell model and its analysis from earlier sections.

Following standard treatment of x-ray scattering of a smectic liquid crystal \cite{12,14}, for a wave vector \(k_z\) near \(k_z = \pm q_0 = \pm 2\pi/a\), the scattering intensity is proportional to the structure function \(S(\tilde{k})\), which is the Fourier transform of the density-density correlation function. The smectic density \(\rho(\vec{r})\) periodic along \(z\) can be represented by

\[
\rho(\vec{r}) = \sum_n \rho_n e^{i q_n [z + u(\vec{r})]},
\]  \tag{120}

where \(q_n = nq_0 = 2n\pi/a\).

From this we obtain:

\[
S(\tilde{k}) \propto n^2 \int d\vec{r} e^{-i\vec{k} \cdot \vec{r}} e^{i q_n z} \langle e^{i q_n [u(\vec{r}) - u(\vec{0})]} \rangle
\]  \tag{121}

Focusing on the lowest order \(n = 1\) peak at \(q_0\), and using a Gaussian approximation for the statistics of \(u\) distortions (expected to be valid on short scales), we find

\[
S(\tilde{k}) \propto \int d\vec{r} e^{-\langle (k_z - q_0) z - i\vec{k}_z \cdot \vec{r} \rangle z - \frac{q_0^2}{15} (|u(\vec{r}) - u(\vec{0})|^2).}
\]  \tag{122}

For smectic distortions confined to the vicinity of the random substrate \cite{42}, the structure function reduces to

\[
S(k_z, \tilde{k}_z) = \int dx dz de^{-i(k_z - q_0) z - i\vec{k}_z \cdot \vec{r}} e^{-\frac{q_0^2}{15} C(x, z)},
\]  \tag{123}

in which \(\tilde{k}_z = k_z - q_0\).

A detailed analysis of the peak requires the full form of the phonon correlation function \(C(x, z)\), which is only available at long scale but is somewhat complicated to analyze. However, as discussed by Chen and Toner \cite{43}, the behavior near and away from the Bragg peak is respectively controlled by long- and short-length-scale correlations.

For \(k_z < \sqrt{\lambda^{-1} k_z}\), the main contribution to the structure function comes from \(x > \sqrt{\lambda} > \xi_z\); thus, approximation \(C(x, z) \approx \pi a^2 x/\xi_z(T)\) can be used. At finite \(k_z\) we thereby have

\[
S(k_z, \tilde{k}_z) \sim S_x(k_z) = \int dx e^{-i k_z x} e^{-2\pi^2 x/\xi_z(T)}
\]

\[
= \frac{4\pi^3/\xi_x(T)}{k_z^2 + 4\pi^3/\xi_x(T)}
\]  \tag{124}

where the peak width is given by \(\Delta k_z = 2\pi^3/\xi_x(T)^{-1} \propto \delta_f(T)\).

For \(\sqrt{\lambda^{-1} k_z} < k_z\), similarly, a long-scale phonon correlation can be approximated as \(C(x, z) \approx \sqrt{2\pi a^2 z/\xi_z(T)}\), and at finite \(k_z\) the structure function in which \(F_C(x)\) and \(F_S(x)\) are Fresnel integrals. Thus, we find that the \(S_x(\tilde{k}_z)\) peak width is given by \(\Delta \tilde{k}_z \propto \sqrt{\lambda^{-1} k_z}\).
Above details of the peak profile are summarized in Fig. 10. We thus predict that the x-ray peak widths along $k_x$ and $\tilde{k}_z$ will broaden with reduced temperature below the CO phase transition temperature $T_g$. This prediction for the finite smectic order characterized by $\xi_{x,z}(T)$ may have already been observed as the aforementioned precipitous x-ray peak broadening in cooled smectic liquid crystal cells with a random substrate [17,18]. More detailed experimental studies are necessary to verify this conjecture.

Away from the Bragg peak, the structure function is dominated by a short-scale correlation, well approximated by $e^{-q^2C(x,z)} \approx 1 - \frac{q^2}{2}C(x,z)$. At large $k_x$ and $\tilde{k}_z$ we thus obtain

$$S(k_x,\tilde{k}_z) \approx \frac{q^2}{2} C(\Delta f k_x, \tilde{k}_z),$$

with limits

$$S(k_x,\tilde{k}_z) \approx \begin{cases} \pi^2 \Delta f \frac{2 B^2 \lambda}{k_x^2} \frac{1}{2 B^2 \lambda a^2} \frac{1}{\tilde{k}_z^3} & \text{for } k_x \ll \sqrt{\frac{1}{\lambda} \tilde{k}_z}, \\ \pi^2 \Delta f \frac{2 B^2 \lambda}{k_x^2} \frac{1}{2 B^2 \lambda a^2} & \text{for } k_x \gg \sqrt{\frac{1}{\lambda} \tilde{k}_z}, \end{cases}$$

as illustrated in Fig. 10.

VII. LIMITS OF VALIDITY

A. Analysis of elastic nonlinearity

So far we have limited our analysis (see Sec. II) of a smectic cell with a random substrate to a harmonic elastic description neglecting the nonlinear elasticity. However, these are known to be important in smectic systems in the presence of thermal [28,46] and quenched random [7,47] fluctuations. In this section, we formulate the treatment of these nonlinearities and estimate their effects in surface disordered smectic cells.

A complete description that includes elastic nonlinearities and random surface pinning (the latter limited to a Larkin harmonic description) is captured by the replicated energy functional

$$[\xi_{x,z}(T)]^{-1} \propto \delta^2 f(T).$$

FIG. 10. (Color online) Structure function from Eqs. (124), (125), and (127), showing the x-ray scattering peak profile at finite $k_x$ and $\tilde{k}_z$ for $T > T_g$ and $T < T_g$, in which the position of the plotted profile function is shown on the Bragg peak by a dashed line in the inset of each figure. The peaks broaden at temperatures below $T_g$. We thus predict that the x-ray peak widths along $k_x$ and $\tilde{k}_z$ will broaden with reduced temperature below the CO phase transition temperature $T_g$. This prediction for the finite smectic order characterized by $\xi_{x,z}(T)$ may have already been observed as the aforementioned precipitous x-ray peak broadening in cooled smectic liquid crystal cells with a random substrate [17,18]. More detailed experimental studies are necessary to verify this conjecture.
\[ H^{(r)} = H_{\text{bulk}} + H_{\text{pin}} \]
\[ = \sum_{\alpha} \int d^{d-2}xdz \int_{0}^{\infty} dy \left\{ \frac{K}{2} (\nabla_{\perp} u^\alpha)^2 + \frac{B}{2} \left[ \partial_z u^\alpha - \frac{1}{2} (\nabla_{\perp} u^\alpha)^2 \right] \right\} \]
\[ - \frac{1}{2T} \sum_{\alpha,\beta} n \int d^{d-2}xdydz \delta(y) \left[ \Delta f \partial_x u_{\alpha 0}^\beta(x,y) \partial_x u_{\beta 0}^\alpha(x,y) + \Delta v u_{\alpha 0}^\beta(x,y) \right] \]
\[ = \sum_{\alpha} \int d^{d-2}xdz \int_{0}^{\infty} dy \left[ \frac{K}{2} (\nabla_{\perp} u^\alpha)^2 + \frac{B}{2} \left( \partial_z u^\alpha \right)^2 \right] \]
\[ - \frac{1}{2T} \sum_{\alpha,\beta} n \int d^{d-2}xdydz \delta(y) \left[ \Delta f \partial_x u_{\alpha 0}^\beta(x,y) \partial_x u_{\beta 0}^\alpha(x,y) + \Delta v u_{\alpha 0}^\beta(x,y) \right] \]
\[ - \sum_{\alpha} \int d^{d-2}xdydz \frac{B}{2} \left( \partial_z u^\alpha \right) (\nabla_{\perp} u^\alpha)^2 + \sum_{\alpha} \int d^{d-2}xdydz \frac{B}{8} (\nabla_{\perp} u^\alpha)^4 \]
\[ \equiv H_0 + H_1. \]

To assess the influence of \( H_1 \) nonlinearities we perform \((d - 1)\)-dimensional coarse-graining at fixed \( y \), perturbatively in \( H_1 \), which allows us to utilize the harmonic correlation function derived in Sec. [IV]

\[ C(q_x, q_z, y) \]
\[ = \frac{\langle |u(q_x, q_z, y)|^2 \rangle}{(T \Gamma_q \delta_{\alpha,\beta} + \frac{\Delta f k_z^2 + \Delta v}{\Gamma_q^2}) \phi^2(q, y),} \]

where \( \phi(q, y) \) is given in Eq. [20]. The lowest nontrivial correction is given by

\[ \delta H = -\frac{1}{2T} \langle H_{1}^2 \rangle = \frac{B^2}{4T} \sum_{\alpha,\beta} \int d^{d-2}xdydz d^{d-2}x'dy'dz' [\partial_x u^\alpha(x, y, z)] [\partial_x u^\beta(x', y', z')] \]
\[ \times \left( \frac{| \nabla_{\perp} u^\alpha(x, y, z) | | \nabla_{\perp} u^\beta(x', y', z') |}{(\nabla_{\perp} u^\alpha)^2} \right)^2, \]

where the correlator of short-scale modes is given by [see

\[ \langle [\partial_x u^\alpha(x, y, z)] [\partial_x u^\beta(x', y', z')] \rangle \]
\[ = \int d^{d-2}k_x dk_z \left( T \delta_{\alpha,\beta} + \frac{\Delta f k_z^2 + \Delta v}{\Gamma_k^2} \right) k_z^2 e^{i k_z (x-x')} \]
\[ \times e^{i k_x (z-z')} \phi(k, y) \phi(k, y'). \]

Redefining variables \( X = (x + x')/2, \delta x = x - x', Z = (z + z')/2, \) and \( \delta z = z - z' \), the dominant contribution is given by

\[ \delta H = \frac{1}{2} \sum_{\alpha} \int d^{d-2}Xdz \int dydy' \delta B(y, y') [\partial_z u^\alpha(X, y, Z)] [\partial_z u^\alpha(X, y', Z)], \]
where

$$\delta B(y, y') = -\frac{B^2}{2T} \int d^d \delta x \delta z \left(\left(\left[\nabla u(x, y, z) \cdot \nabla u\right](x', y', z')\right)\right)^2$$

$$= -\frac{B^2}{2T} \int \frac{d^d k_x}{(2\pi)^d} \frac{d_k z}{2\pi} \left(\frac{T}{\Gamma_k} + \frac{\Delta \kappa^2 + \Delta_0}{\Gamma_k^2}\right)^2 k^2 \phi^2(k, y')$$

$$\approx -\frac{B^2}{2T} \int \frac{d^d k_x}{(2\pi)^d} \frac{d_k z}{2\pi} \left(\frac{T}{\Gamma_k} + \frac{\Delta \kappa^2 + \Delta_0}{\Gamma_k^2}\right)^2 k^2 \phi^2(k, y').$$

(134)

(135)

The Fourier transform with respect to X and Z, \(\delta B(q)\) gives

$$\delta H = \frac{1}{2} \sum q \left(\frac{d^d q_x}{(2\pi)^d} \int \frac{d d y \delta B(y, y') \phi(q, y) \phi(q, y')}{q^2 |u^\alpha_0(q)|^2}\right)$$

$$= \frac{1}{2} \sum q \left(\frac{d^d q_x}{(2\pi)^d} \int \delta B(q) q^2 |u^\alpha_0(q)|^2\right),$$

(136)

in which the momentum-dependent correction to the smectic compressional modulus in the effective surface theory, \(\delta B(q)\), is given by

$$\delta B(q) = \int \frac{d^d y \delta B(y, y') \phi(q, y) \phi(q, y')}{q^2 |u^\alpha_0(q)|^2},$$

(137)

with the function \(b(q,k)\) given by

$$b(q,k) = \int_0^\infty d y \phi^2(k, y) \phi(q, y).$$

(138)

We thus obtain the effective randomly surface pined smectic model that includes the effect of smectic nonlinear elasticity. Although formally well defined, so far we have not succeeded in systematically treating this correction analytically. We leave such an analysis to future studies.

Focusing on the leading exponential contribution allows us to carry out y and y' integrals, giving

$$\delta B(q) \approx -B^2 \int \frac{d^d k_x}{(2\pi)^d} \frac{d_k z}{2\pi} \left(\frac{T}{\Gamma_k} + \frac{\Delta \kappa^2 + \Delta_0}{\Gamma_k^2}\right)^2 k^2 \phi^2(k),$$

(139)

where \(D(q) = \frac{1}{2\sqrt{2}} \sqrt{\lambda^2 q^2 + \lambda^2 + \lambda q^2}\), and, thus, in the \(q \to 0\) limit it gives

$$\delta B(q \to 0) \approx \delta B_0 = -B^2 \int \frac{d^d k_x}{(2\pi)^d} \frac{d_k z}{2\pi} \left(\frac{T}{\Gamma_k} + \frac{\Delta \kappa^2 + \Delta_0}{\Gamma_k^2}\right)^2 k^2 \phi^2(k),$$

(140)

Equating \(\delta B_0 q^2\) to the harmonic kernel in Eq. (28) allows us to define nonlinear crossover length \(\xi_{NL,x}\) beyond which nonlinear elastic effects must be taken into account. Focusing on orientational pinning (that we showed is dominant at long scales, see Sec. V), we find

$$\delta B_0 q^2 \approx -B \int \frac{d^d k_x}{(2\pi)^d} \frac{d_k z}{2\pi} \left(\frac{T}{\Gamma_k} + \frac{\Delta \kappa^2 + \Delta_0}{\Gamma_k^2}\right)^2 k^2 \phi^2(k),$$

(141)

as the length above which the nonlinear elasticity dominates [43].

Based on this we expect that although nonlinear elasticity is relevant below \(d^d = 4\) for the orientational pinning, it is only relevant at length scales much larger than the (Larkin) domain size \(\xi_x\). Thus, to study system properties at length scales smaller than the nonlinear length \(\xi_{NL,x}\), it is safe to ignore the nonlinear elasticity. Here we employed this approximation and left the full analysis of nonlinear elasticity for future study [49].

B. Stability of orientational order

All of the above analysis of smectic (positional) order was predicated on the assumption that the long-range nematic (orientational) order is stable. Below we examine this assumption.

In the limit of dominant orientational pinning, the mean-squared distortion of orientational order on the heterogeneous substrate at \(y = 0\) is given by

$$\left\langle \left|\delta n(x)\right|^2 \right\rangle \approx \left\langle \left|\phi(x)\right|^2 \right\rangle$$

$$= \Delta_f \int \frac{d^d q_x}{(2\pi)^d} q^2 \frac{1}{\Gamma_q}$$

$$= \frac{(\pi - 2)\Delta_f}{4\pi^2 \beta^2 L^d} \int_0^{1/a} d q_x$$

$$\approx \Delta_f \frac{a}{\beta^2 L^d} \frac{1}{\xi_x} \ll 1.$$  

(143)

Evidently, orientational order is indeed long ranged for weak orientational pinning.

In contrast, we find that for dominant positional pinning, the distortion of nematic director diverges at
long scales according to
\[
\langle |\delta n(x)|^2 \rangle \approx \langle |\partial_x u_0(x, z)|^2 \rangle = \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \int \frac{d\xi_x}{\sqrt{1/|L|^2}} \\
\approx \frac{(\pi - 2) \Delta_v}{4 \pi^2 B^2 \lambda^3} \frac{1}{L}. \tag{144}
\]
This implies that the orientational order is destroyed at scales above
\[
\xi_{O,x} = \frac{cB^2 \lambda^3}{\Delta_v} = \frac{1}{3}(\xi_v^3/a^2) \gg \xi_v, \tag{145}
\]
set by the condition on \( L \) such that \( \delta n \approx 1 \). Similarly, along \( z \), the length scale beyond which the mean squared orientational distortion \( \langle |\delta n(x)|^2 \rangle \) grows to order 1 is
\[
\xi_{O,z} \approx \left( \frac{cB^2 \lambda^5/2}{\Delta_v} \right)^2 \sim \xi_{O,x}/\lambda \gg \xi_v. \tag{146}
\]
Naively this purely harmonic calculation implies that the analysis and prediction of previous sections are only valid up to this finite nematic domain scale, \( \xi_{O,x} \) and \( \xi_{O,z} \). However, based on Eq. \([100]\) and the supporting RG and matching analysis, we note that at long scales the positional pinning becomes dominant to purely orientational pinning, whether it is relevant for \( T < T_g \) or irrelevant for \( T > T_g \) (in the former case just modifying the strength of the effective orientational pinning). Thus, we conclude based on this and Eq. \([143]\) that the orientational order is indeed stable for weak smectic surface pinning.

\section*{VIII. SMECTIC CELL WITH HOMEOTROPIC ALIGNMENT}

So far our focus has been on a smectic cell in the bookshelf geometry, corresponding to molecular alignment parallel to the substrate, with the smectic layer normal lying in the plane of the substrate. As we demonstrated in previous sections, random surface pinning in this geometry has significant qualitative effects on the smectic order, even in the bulk of the cell, destabilizing it on a random substrate.

In this section, for completeness, we also analyze a cell with a homeotropic alignment, with smectic layers running parallel to the substrate. As we show below, in this geometry the problem reduces to that of a surface-pinned \( xy \) model. It thereby maps onto the previously studied planar nematic order with surface random pinning \([10, 11]\).

In this homeotropic geometry the cell is described by the Hamiltonian
\[
H_{sm} = \int d^{d-1}x \int_0^w dz \left[ \frac{K}{2}(\nabla^2 u)^2 + \frac{B}{2}(\partial_z u)^2 \right] + H_{pin}, \tag{147}
\]
with the layer normal \( \hat{z} \) perpendicular to the substrate. Substrate randomness introduces distortions in the preferred layer normal
\[
\hat{n} = (\delta n_x, \delta n_y, \hat{z})/\sqrt{1 + \delta n_x^2 + \delta n_y^2}, \tag{148}
\]
leading to pinning energy
\[
H_{pin} = \int d^{d-1}xdz \{ -W(\hat{n} \cdot \hat{z})^2 - [\hat{n} \cdot \mathbf{g}(r)]^2 - V(u, r) \} \\
\approx \int d^{d-1}xdz \{ - W + \frac{W}{2}(\delta n_x^2 + \delta n_y^2) - \mathbf{h}(\mathbf{x}) \cdot \delta \mathbf{n} - V(u, \mathbf{x}) \} \\
\approx \int d^{d-1}xdz \left[ \frac{W}{2}(\nabla_\perp u)^2 - \mathbf{h}(\mathbf{x}) \cdot (\nabla_\perp u) - V(u, \mathbf{x}) \right]. \tag{149}
\]
Above we made use of the approximate relation between gradient of the smectic layers and the nematic director deviation \( \delta \mathbf{n} = (\delta n_x, \delta n_y, 0) \approx \nabla_\perp \mathbf{u} \), and in the last equation ignored irrelevant constants. The first pinning term encodes the average substrate homeotropic alignment, \( [\hat{n} \cdot \mathbf{g}(\mathbf{r})]^2 \sim \mathbf{h}(\mathbf{x}) \cdot (\nabla_\perp \mathbf{u}) \) captures the random orientational pinning on the substrate, and the last term is the random positional pinning at \( z = 0 \).

As for the bookshelf geometry, it is convenient to carry out the dimensional reduction to the surface field \( u(x, y, z)|_{z=0} = u_0(x, y) \) at \( z = 0 \) in a half-infinite cell. To this end we solve the corresponding Euler-Lagrange equation subject to the substrate boundary condition
\[
K\nabla_\perp^4 u(x, y, z) - B\partial^2_z u(x, y, z) = 0,
\]
whose solution for a thick cell is given by
\[
u_0(\mathbf{q}) = u_0(\mathbf{q})e^{-\lambda q^2 z}. \tag{150}
\]
Plugging this back into the bulk Hamiltonian and integrating over the \( z \) degrees of freedom for \( z > 0 \), we obtain the effective surface Hamiltonian
\[
H_{sm}^{surf} = \int \frac{d^2q}{(2\pi)^2} \Gamma_0 \frac{\Delta_q}{2} q^2 |u_0(q)|^2 \\
- \int d^{d-1}xdz \{ \mathbf{h}(\mathbf{x}) \cdot (\nabla_\perp u) + V(u, \mathbf{x}) \}, \tag{151}
\]
where
\[
\Gamma_0 = \sqrt{KB} + W. \tag{152}
\]
In the momentum space the random pinning is given by
\[
H_{pin} = -\int \frac{d^2q}{(2\pi)^2} [\mathbf{q} \cdot \mathbf{h}(-\mathbf{q})u_0(\mathbf{q}) + f(-\mathbf{q})u_0(\mathbf{q})]. \tag{153}
\]
Thus, as anticipated in the Introduction, in this homeotropic geometry the effects of the random substrate in a smectic cell reduce to that of a well-studied random-field 2D $xy$-model for the displacement of the smectic layer in contact with the random substrate. In a weak pinning limit (where effects of dislocations and of nonlinear elasticity can be safely neglected) it is predicted to lead to weak breakdown of long-ranged smectic order with log-squared phonon correlations \[22, 27, 33, 37, 50\]. The random substrate pinning is significantly less disruptive in this geometry and can be used to test numerous theoretical predictions for the 2D random-field $xy$-model \[10, 11\].

**IX. CONCLUSIONS**

**A. Summary**

Motivated by a number of liquid crystal experiments on smectic cells \[17, 18\], in this paper we studied the smectic liquid crystal order perturbed by a randomly heterogeneous substrate. Demonstrating that the resulting random surface pinning comes in two, orientational and positional, forms, we introduced a general model for a heterogeneous smectic cell and analyzed the response and stability of its smectic order to a random substrate. We thereby demonstrated rigorously that smectic long-range order in a thick cell (without a rubbed substrate) at long scales is unstable to arbitrarily weak surface disorder, replaced by random smectic domains whose size and correlations on the heterogeneous substrate and in the bulk we have computed. We showed that for weak random pinning the smectic order is thereby replaced by a three-dimensional smectic-glass-like state, that undergoes a temperature and pinning-driven Cardy-Ostlund-like phase transition between a high-temperature weakly-pinned smectic and a low-temperature smectic glass, where smectic layers in bookshelf geometry are strongly pinned by the dirty substrate.

We computed the statistics of the induced positional and orientational distortions within and on scales beyond the smectic domains. We also analyzed the transmission signal in the polarized light microscopy and the x-ray scattering structure function in such a smectic cell. We showed that these can be used to experimentally probe our predictions of the finite smectic correlation length and the statistics of the substrate induced smectic textures. Based on this, we suggested that the precipitous broadening of the x-ray peak with reduced temperature observed by Jones and Clark \[17, 18\] may be associated with the predicted smectic glass phase transition. More systematic experimental and theoretical studies are necessary to explore this further. Finally, we also demonstrated that in the geometry where layers run parallel to the random substrate, the distortions on the substrate are governed by the well-studied 2D random-field $xy$-model.

**B. Future directions**

While our current study makes significant progress toward understanding of randomly surface-pinned smectics, it also stimulates a number of interesting open questions that we leave to future research. Probably the most challenging of these is the nature of the locally smectic state in the presence of strong random surface pinning. This regime will exhibit distortions beyond the elastic approximation, resulting in the proliferation of dislocations that are notoriously difficult to treat analytically, requiring sophisticated numerical analysis.

A more systematic (e.g., RG) treatment of nonlinear elasticity, which we only briefly touched on via a self-consistent scaling analysis, is another challenging problem requiring a simultaneous treatment of pinning and elastic anharmonicities.

Throughout this manuscript we have also assumed that the average strain of the pinned smectic state vanishes. While this is true in equilibrium, experimental observations \[17, 18, 52\] suggest that the system may have difficult time equilibrating as the bulk layer spacing changes significantly with temperature, while the layers remain pinned at the random substrate. Thus, as the system is cooled into the smectic state, we expect a significant build up of strain near the random substrate, with the relaxation rate limited by nucleation and motion of edge dislocations. It is clear that accounting for this background strain is crucial for a detailed understanding of current experiments \[17, 18\]. We are currently exploring this interesting effect \[49\].

Finally, our earlier work on nematic cells \[10, 11\] and current study of smectic cells \[12\] lend themselves to generalizations to a broad array of other liquid-crystal phases, such as, for example the cholesteric and smectic-$C$ states. The effect of the random substrate depends qualitatively on the nature of the phases and we leave their analysis to future studies.

We hope that the present study will stimulate further theoretical and experimental work on these and many other open questions.

Appendix A: Solution of the Euler-Lagrange equation

In this appendix, we study the solution to the Euler-Lagrange equation of the smectic liquid crystal cells subject to a boundary condition of a random surface texture \( u(x, y = 0, z) = u_0(x, z) \) or equivalently random force \( f(x, z) \) as in [22],

\[
K \nabla_x^4 u - B \partial_z^2 u = f(x, z) \delta(y),
\]

where we used a surface pinning force

\[
H_{\text{pin}} = - \int dx dy dz \delta(y) f(x, z) u(x, y, z),
\]

(A1)

to encode the boundary condition \( u(x, y = 0, z) = u_0(x, z) \).

In Fourier space Eq. (24) reduces to

\[
\int \frac{dq_x q_y}{2\pi^2} e^{iq_x x + iq_y y} \partial_q \int dq_x dq_y \mathcal{P} e^{iq x + iq_y y} (q_x^2 + q_y^2)^2 + B q_z^2)
\]

giving

\[
u(q_x, q_y) = \frac{f(q_x, q_y)}{K (q_x^2 + q_y^2)^2 + B q_z^2},
\]

(A2)

Thus, for \( y > 0 \) we have

\[
u(q_x, q_z, y) = \int_{-\infty}^{\infty} dq_y \frac{f(q_x, q_y) e^{iq_y y}}{2\pi K (q_x^2 + q_y^2)^2 + B q_z^2}
\]

\[
= \frac{f(q_x, q_y)}{2\pi B\sqrt{\lambda}} \frac{dq_y}{\pi} e^{iq_y y} (q_x^2 + q_y^2)^2 + q_z^2
\]

(A4)

with the associated length \( \lambda = \sqrt{K/B} \). As shown in Fig. [11] [24] can be readily evaluated by use of a contour integration, closing the contour in the upper half of the complex plane. Defining \( q_p = \sqrt{-\lambda q_x^2 + i q_z} \), the four poles are given by \( \pm q_p \) and \( \pm q_p^* \). Closing the contour in the upper half-plane, we find

\[
\int_{-\infty}^{\infty} dq_y \frac{f(q_x, q_y) e^{iq_y y}}{2\pi B\sqrt{\lambda}} \frac{dq_y}{\pi} e^{iq_y y} (q_x^2 + q_y^2)^2 + q_z^2
\]

(A5)

and

\[
q_p^2 = -\lambda q_x^2 + i q_z = \left| q_p \right|^2 e^{i \left( \pi - \arctan \left( \frac{q_p}{\lambda q_z^2} \right) \right)},
\]

(A6)

We find

\[
q_p = (\lambda^2 q_x^4 + q_z^2)^{1/4} e^{i \left( \pi - \frac{1}{2} \arctan \left( \frac{q_z}{\lambda q_x^2} \right) \right)},
\]

(A7)

\[
\text{Re}(q_p) = (\lambda^2 q_x^4 + q_z^2)^{1/4} \sin \left( \frac{1}{2} \arctan \left( \frac{q_z}{\lambda q_x^2} \right) \right)
\]

(A8)

\[
\text{Im}(q_p) = (\lambda^2 q_x^4 + q_z^2)^{1/4} \cos \left( \frac{1}{2} \arctan \left( \frac{q_z}{\lambda q_x^2} \right) \right)
\]

(A9)
u(q_x, q_z, y) = \frac{f(q_x, q_z)}{2B\sqrt{2\lambda}} \frac{1}{q_z \sqrt{\lambda^2 q_x^2 + q_z^2}} e^{-\frac{\sqrt{\lambda^2 q_x^2 + q_z^2 + \lambda q_z^2}}{2B\sqrt{2\lambda}}} \times \left[ \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \cos \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \right) + \sqrt{\lambda^2 q_x^2 + q_z^2 + \lambda q_z^2} \sin \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \right) \right]. \quad (A10)

FIG. 11. (Color online) The integral [A1] represented by a contour integral closed in the upper-half of the complex plane with poles shown.

On the y = 0 substrate,

\[ u_0(q_x, q_z) = u(q_x, q_z, y = 0) = \frac{f(q_x, q_z)}{2B\sqrt{2\lambda}} \frac{1}{q_z \sqrt{\lambda^2 q_x^2 + q_z^2}} \times \left[ \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \cos \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \right) + \sqrt{\lambda^2 q_x^2 + q_z^2 + \lambda q_z^2} \sin \left( \frac{y}{\sqrt{2\lambda}} \sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2} \right) \right]. \quad (A11) \]

Combining this with Eq. [A10] allows us to express \( u(q_x, q_z, y) \) in terms of this substrate deformation

but not both. The calculation here is only precise in the scaling sense and is not quantitatively accurate.

1. Larkin lengths for dominant surface orientational pinning

Focusing on the case of dominant random orientational disorder and generalizing the analysis to d dimensions with \((d-2)\)-dimensional x, we find that the smectic phonon variance is given by

\[ \langle u_0^2(x, z) \rangle = \frac{\Delta_f}{2B^2\lambda} \int d^{d-2}q_x dq_z \frac{\sqrt{\lambda^2 q_x^2 + q_z^2 - \lambda q_z^2}}{(2\pi)^{d-1}q_x^2} \frac{1}{q_z^2(\lambda^2 q_x^2 + q_z^2)}. \quad (B1) \]

This integral is divergent at small q and needs cutoffs set by the domain size \( L_x \) and \( L_z \). For \( L_x \ll \sqrt{\lambda L_z} \), one can integrate \( q_x \) out, cut off the IR integration by \( q_x \sim 1/L_x \), and find

\[ \langle u_0^2(x, z) \rangle = \frac{\Delta_f}{4\pi B^2\lambda^3} \int d^{d-2}q_x \frac{\pi - 2}{(2\pi)^{d-2} \lambda^2 q_x^2} \]

diverging for \( d < d_{lc} = 4 \), where \( S_d \) is the surface area of a d-dimensional unit sphere, and \( C_d = S_d/(2\pi)^d \). Defining the Larkin domain size \( \xi_f^d \) as the length scale over which

\[ \begin{aligned}
\Delta_f &= \frac{\Delta_f}{4\pi B^2\lambda^3} \int d^{d-2}q_x \frac{1}{4 - d} L_x^{4-d},
\end{aligned} \quad (B2) \]

Appendix B: Domain size in the surface disordered smectic cell in bookshelf geometry

In this appendix we present the details of the analysis of the Larkin lengths setting the domain size and shape within which smectic order is stable and the weak random pinning is treated perturbatively. To make analytical progress we focus on extreme limits of dominant positional pinning \( \Delta_v \) or dominant orientational pinning \( \Delta_f \),
$u_{rms}$ is on the order of smectic layer spacing, we find

$$\xi_z^f = \left[ \frac{4(4-d)\pi}{(\pi-2)C_{d-2}} \frac{B^2\lambda^d q_x^2}{\Delta_f} \right]^{1/(4-d)},$$

which for the physically relevant case of $d = 3$ is given by

$$\xi_z^f = c \frac{B^2\lambda^3 a^2}{\Delta_f},$$

in which $c = \frac{4\pi^2}{\pi-2} \approx 34.6$. At the lower critical dimension of $d = 4$, $u_{rms}$ diverges logarithmically leading to

$$\xi_z^f = a \exp \left[ \frac{4\pi}{\pi-2} \frac{(2\pi)^2 B^2\lambda^3 a^2}{S_2} \right].$$

Similarly for the Larkin length along $z$, integrating over $q_x$ first, we find

$$\langle u_0^z(x,z) \rangle = \frac{\Delta_f}{2B^2} \int \frac{dq_x}{2\pi} \int \frac{dq_{x}^{d-2}}{2\pi} \frac{d}{q_x^{d-2}} \frac{\sqrt{\lambda^d q_x^2 + \lambda^2 q_z^2 - \lambda q_z^2}}{q_x^2(\lambda^d q_x^4 + q_z^4)}$$

$$= \frac{\Delta_f}{2B^2} S_{d-2} \int \frac{dq_x}{2\pi} \int_0^{\infty} \frac{\sqrt{\lambda^d q_x^2 + \lambda^2 q_z^2 - \lambda q_z^2}}{q_x^2(\lambda^d q_x^4 + q_z^4)} q_x^{d-1} dq_x$$

$$= \frac{\Delta_f}{2\pi B^2\lambda^{d/2+1}} \frac{S_{d-2}}{(2\pi)^{d-2}} \Gamma\left(\frac{1}{2} - \frac{d}{2}\right) \Gamma\left(\frac{d}{2}\right) - \pi^{3/2} \sec\left(\frac{\pi}{4}\right)$$

$$\times \int_1^{1/a} dq_z q_z^{d-3}$$

$$= \frac{1}{B(d)} \frac{\Delta_f}{2B^2 d^{2-d/2}} L_z^{2-d/2},$$

in which

$$\frac{1}{B(d)} = \frac{1}{\pi} \frac{S_{d-2}}{(2\pi)^{d-2}} \Gamma\left(\frac{1}{2} - \frac{d}{2}\right) \Gamma\left(\frac{d}{2}\right) - \pi^{3/2} \sec\left(\frac{\pi}{4}\right).$$

This gives

$$\xi_z^f = \left[ (4-d)B(d) \frac{B^2\lambda^{d/2+1} a^2}{\Delta_f} \right]^{2/(4-d)},$$

which in the physically relevant three dimensions reduces to

$$\xi_z^f = \left[ B(3) \frac{B^2\lambda^{3/2} a^2}{\Delta_f} \right]^2,$$

where $B(3) \approx 37.5$ is roughly the same as $c$. At the lower critical dimension we instead find

$$\xi_z^f = a \exp \left[ \frac{2}{B(4)} \frac{B^2\lambda^3 a^2}{\Delta_f} \right].$$

2. Larkin lengths for dominant surface positional pinning

For a smectic cell where positional disorder dominates, the variance of smectic distortions is given by

$$\langle u_0^z(x,z) \rangle = \int \frac{dq_x}{2\pi} \int_0^{\infty} \frac{dq_z}{2\pi} \frac{\Delta_v}{\pi} \frac{\sqrt{\lambda^2 q_x^2 + \lambda^2 q_z^2 - \lambda q_z^2}}{q_x^2(\lambda^2 q_x^4 + q_z^4)}$$

$$= \frac{\Delta_v}{4\pi B^2} \frac{\Delta_v}{\pi} \int \frac{dq_x}{2\pi} \frac{\Delta_v}{\pi} \int_0^{1/a} \frac{dq_z}{q_z^2}$$

$$= \frac{(\pi-2)\Delta_v}{12\pi B^2\lambda^3} \left[ \frac{\pi}{L_z} \right]^3,$$

which diverges as $L_z^3$ in 3D.

Consequently, the Larkin length along $x$ is given by

$$\xi_x^v = \left[ 3c \frac{B^2\lambda^3 a^2}{\Delta_v} \right]^{1/3}.$$

Similarly, the Larkin length along $z$ is instead given by

$$\xi_z^v = \left[ A(3) \frac{B^2\lambda^3 a^2}{\Delta_v} \right]^{2/3},$$

where $A(3) = \frac{12\pi^2}{10\pi^2 - \frac{\sqrt{2}}{2}} \approx 39.83$, roughly the same as $c$.

More generally in $d$ dimensions the variance is given by

$$\langle u_0^v(x,z) \rangle = \frac{\Delta_v}{4\pi B^2} \frac{\Delta_v}{\pi} \int \frac{dq_x}{(2\pi)^{d-2}} \frac{\Delta_v}{\pi} \int \frac{dq_z}{q_z^2}$$

$$= \frac{(\pi-2)\Delta_v}{4\pi B^2} \frac{S_{d-2}}{(2\pi)^{d-2}} \int \frac{dq_z}{q_z^2}$$

$$= \frac{(\pi-2)\Delta_v}{4\pi B^2} \frac{S_{d-2}}{(2\pi)^{d-2}} \int \frac{dq_z}{q_z^2}$$

$$= \frac{(\pi-2)\Delta_v}{4\pi B^2} \frac{S_{d-2}}{(2\pi)^{d-2}} \int \frac{dq_z}{q_z^2}$$

which is diverging for $d < d_v^e = 6$, leading to the Larkin length along $x$ given by

$$\xi_x^v = \left[ \frac{(6-d)\pi}{(\pi-2)C_{d-2}} \frac{B^2\lambda^{d/2} a^2}{\Delta_v} \right]^{1/(6-d)}.$$

And similarly along $z$

$$\xi_z^v = \left[ \frac{(6-d)\pi}{(\pi-2)C_{d-2}} \frac{B^2\lambda^{d/2} a^2}{\Delta_v} \right]^{2/(6-d)},$$

in which

$$\frac{1}{\Delta_v} = \frac{1}{\pi} \frac{S_{d-2}}{(2\pi)^{d-2}} \Gamma\left(\frac{1}{2} - \frac{d}{2}\right) \Gamma\left(\frac{d}{2}\right) - \pi^{3/2} \csc\left(\frac{\pi}{4}\right).$$

At the lower critical dimension $d = 6$, $u_{rms}$ diverges logarithmically, leading to

$$\xi_x^v = a \exp \left[ \frac{4\pi}{\pi-2} \frac{B^2\lambda^3 a^2}{S_4} \right],$$

$$\xi_z^v = a \exp \left[ \frac{2A(6) B^2\lambda^3 a^2}{3 \Delta_v} \right].$$
Appendix C: Calculation of correlation functions at short scales (Larkin regime)

Here we present the details of the correlation function of smectic phonons \( u_0(x, z) \) on the dirty substrate, \( y = 0 \), focusing on the short-scale Larkin regime. In 3D it is given by a Fourier transform of Eq. (48),

\[
C(x, z) = \langle [u_0(x, z) - u_0(0, 0)]^2 \rangle = \int dq_x dq_z \Delta_f q_x^2 + \Delta_x (1 - e^{iq_x x + iq_z z}),
\]

where within the Larkin regime the integrations are bounded by the intermediate length scales \( \xi_{x,z} \) given in Sec. [V.B]. We treat the two forms of orientational and positional pinnings individually, for simplicity assuming one or the other (but not both) dominates.

1. Dominant surface orientational disorder

With dominant surface orientational disorder, the correlation function is given by

\[
C_f(x, z) = \langle [u_0(x, z) - u_0(0, 0)]^2 \rangle = \int dq_x dq_z \Delta_f q_x^2 \sqrt{\lambda^2 q_x^2 + q_z^2} - \lambda q_x^2 q_z^2 (1 - e^{iq_x x + iq_z z}).
\]

For the dependence along \( x \), we first integrate out \( q_z \), obtaining (for \( x \ll \xi_x \))

\[
C_f(x, 0) \approx 2 \left( \frac{\pi}{2} - 2 \right) \Delta_f \int_{1/\xi_x}^{\infty} q_x^{-2} \frac{1 - \cos(q_x x)}{2} dq_x \approx \frac{\pi a^2 x}{\xi_x^3}.
\]

For the dependence along \( z \), we instead have

\[
C_f(0, z) \approx \frac{a^2}{2} \int_{1/\xi_x}^{\infty} dq_z \frac{1 - \cos(q_z z)}{q_z^{3/2}} \approx \sqrt{2\pi a^2} \frac{z}{\xi_x^3},
\]

where the definition of \( \xi_{x,z}^f \) is given in Sec. [V.B]. These correlation functions with dominant orientational disorder are plotted in Fig. [3].
where the definition of $\xi_\alpha^i$ from Sec. [14] was used. The correlation functions with dominant positional disorder are plotted in Fig. 4.

As discussed in the main body of the paper, the validity of this perturbative analysis is limited to short scales of the Larkin regime. To understand the behavior at longer distance, where the Larkin treatment breaks down, we utilize the renormalization group analysis.

### Appendix D: FRG analysis to the second order

In this appendix we present the details of the FRG analysis by evaluating each term in Eq. (83). Averaging over the high-wave-vector fields in the surface orientational disorder term in Eq. (83) we find

\[
\langle H_{\Delta f} \rangle = \frac{1}{4T} \sum_{\alpha, \beta} \int d^d x dz \int_k \tilde{\Delta}_f(k) \left( e^{ik u_0^\alpha(x,z)} - u_0^\alpha(x,z) \right) \left( \partial_x \left[ u_0^\alpha(x,z) - u_0^\beta(x,z) \right] \right)^2 \rightangle
\]

\[
= \frac{1}{4T} \sum_{\alpha, \beta} \int d^d x dz \int_k \tilde{\Delta}_f(k) e^{ik u_0^\alpha(x,z)} \left( \partial_x \left[ u_0^\alpha(x,z) - u_0^\beta(x,z) + u_0^\beta(x,z) - u_0^\beta(x,z) \right] \right)^2 \rightangle
\]

\[
= \frac{1}{4T} \sum_{\alpha, \beta} \int d^d x dz \int_k \tilde{\Delta}_f(k) e^{ik u_0^\alpha(x,z)} \left( \partial_x \left[ u_0^\alpha(x,z) - u_0^\beta(x,z) \right] \right)^2 \rightangle,
\]

in which the cross term is linear in $u_0^\alpha$ and, thus, vanishes in momentum-shell RG. The key part of the first term in the above equation is

\[
\langle e^{ik u_0^\alpha(x,z)} - u_0^\alpha(x,z) \rangle = \frac{1}{Z_0^\alpha} \int [d u_0^\alpha] e^{ik u_0^\alpha(x,z)} e^{-H_0^\alpha / T}
\]

\[
e^{-\kappa^2 f_{\alpha, \beta}},
\]

in which $Z_0^\alpha$ is the partition function of the high-wave vector components of the system

\[
Z_0^\alpha = \int [d u_0^\alpha] e^{-H_0^\alpha / T},
\]

and $f_{\alpha, \beta}$ is given by

\[
f_{\alpha, \beta} = C_{T, \alpha, \alpha}(0) - C_{T, \alpha, \beta}(0)
\]

\[
= \int_{\Lambda e^{-\delta \ell}}^{\Lambda} \frac{d^d - 2 q_z}{(2\pi)^{d-2}} \int_0^\infty \frac{dq_z}{2\pi} \frac{T}{\Gamma_q} (1 - \delta_{\alpha, \beta})
\]

\[
\equiv \eta(1 - \delta_{\alpha, \beta}) \delta \ell.
\]

For $d = 3$ it is easy to show that $\eta = \frac{T}{2\pi B T}$, which is a constant under the renormalization flow. We can see that with the expansion $e^{-\kappa^2 f_{\alpha, \beta}} = 1 - \kappa^2 f_{\alpha, \beta} + \cdots$, the zeroth-order term contributes through rescaling and the first-order term leads to the random orientational pinning nonlinearity

\[
\delta \Delta^{(1)}(u) = \eta \Delta^\prime(u) \delta \ell,
\]

with $\prime$ indicating derivation respect to $u$.

Clearly, the average in the last term of Eq. (D1) contributes to the surface positional pinning nonlinearity $R_s(u)$. To lowest order, we calculate the average

\[
\left\langle \frac{e^{ik u_0^\alpha(x,z)} - u_0^\alpha(x,z)}{\partial_x \left[ u_0^\alpha(x,z) - u_0^\beta(x,z) \right] \right)^2 \rightangle
\]

\[
\approx \left\langle \frac{\partial_x \left[ u_0^\alpha(x,z) - u_0^\beta(x,z) \right] \right)^2 \rightangle
\]

\[
= 2 \int_{\Lambda e^{-\delta \ell}}^{\Lambda} \frac{d^d - 2 q_z}{(2\pi)^{d-2}} \int_0^\infty \frac{dq_z}{2\pi} \frac{T}{\Gamma_q} (1 - \delta_{\alpha, \beta})
\]

\[
\equiv 2\zeta(1 - \delta_{\alpha, \beta}) \delta \ell,
\]

while for $d = 3$ we have $\zeta = \frac{\Lambda^2}{2\pi B T}$, which contributes

\[
\delta R_s^{(1)}(u) = -\zeta \Delta_f(u) \delta \ell.
\]

We now consider the surface positional disorder in Eq. (83).
\begin{equation}
\langle H_{\Delta v} \rangle > \\
= - \sum_{\alpha, \beta} \frac{1}{2T} \int d^{d-2} x dz \left\langle R_v \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right] \right\rangle > \\
\approx - \sum_{\alpha, \beta} \frac{1}{2T} \int d^{d-2} x dz \left\langle R_v \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right] + \frac{1}{2} R_v'' \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right] \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right]^2 \right\rangle > \\
= - \sum_{\alpha, \beta} \frac{1}{2T} \int d^{d-2} x dz \left\{ R_v \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right] + \frac{1}{2} R_v'' \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right] \left[ u_0^\alpha (x, z) - u_0^\beta (x, z) \right]^2 \right\} > ,
\end{equation}

\text{(D8)}

in which the first term gives a correction through rescaling, the linear order term in $u_0^\alpha >$ makes a vanishing contribution, and the last term

$$\delta R_v^{(1b)}(u) = \eta R_v''(u) \delta \ell,$$

(together with Eq. (D7)) gives a first-order contribution to the surface positional disorder.

To study the second-order contribution in the RG, we start with the $(R_v)^2$ term in (S3) and obtain

$$- \frac{1}{2T} \langle H_{\Delta v}^2 \rangle > = - \frac{1}{(2T)^3} \sum_{\alpha_1, \beta_1, \alpha_2, \beta_2} \int d^{d-2} x dz \int d^{d-2} x' dz' \left\langle R_v \left[ u_0^{\alpha_1} (x, z) - u_0^{\beta_1} (x, z) \right] R_v \left[ u_0^{\alpha_2} (x', z') - u_0^{\beta_2} (x', z') \right] \right\rangle > \\
= - \frac{1}{8T^3} \sum_{\alpha_1, \beta_1, \alpha_2, \beta_2} \int_x \int_{x'} \int_z \int_{z'} R_v'' \left[ u_0^{\alpha_1} (x, z) - u_0^{\beta_1} (x, z) \right] R_v'' \left[ u_0^{\alpha_2} (x', z') - u_0^{\beta_2} (x', z') \right] \\
\times \frac{1}{4} \left\{ u_0^{\alpha_1} (x, z) - u_0^{\beta_1} (x, z) \right\}^2 \left[ u_0^{\alpha_2} (x', z') - u_0^{\beta_2} (x', z') \right]^2 \right\rangle > ,
\end{equation}

\text{(D10)}

in which the average is given by

$$\frac{1}{4} \left\{ u_0^{\alpha_1} (x, z) - u_0^{\beta_1} (x, z) \right\}^2 \left[ u_0^{\alpha_2} (x', z') - u_0^{\beta_2} (x', z') \right]^2 \right\rangle > \\
= [C_T^2 (\delta x, \delta z)]^2 (\delta_{\alpha_1 \alpha_2} + \delta_{\alpha_1 \beta_2} \delta_{\beta_1 \beta_2} - \delta_{\alpha_1 \beta_2} \delta_{\beta_1 \beta_2}),
\end{equation}

\text{(D11)}

where $\delta x = x - x'$ and $\delta z = z - z'$, and the three replica correction contributed by the $\delta_{\alpha_1 \alpha_2}$ term is irrelevant relative to the two-replica terms and is, thus, neglected. The second-order contribution from the random positional pinning then becomes
with

\[ A \delta \ell = \frac{2}{4T^2} \int_{\delta x, \delta z} \left[ C_T^2 (\delta x, \delta z) \right]^2 = \frac{1}{4T^2} \int_{\Lambda_{e-\delta t}}^\Lambda \frac{d^d-2q}{(2\pi)^{d-2}} \int_{-\infty}^\infty dq_z \frac{T^2}{2\pi |q|^2}, \]  

(D13)

and

\[ A_2 \delta \ell = \frac{1}{4T^2} \int_{\delta x, \delta z} (\delta x)^2 \left[ C_T^2 (\delta x, \delta z) \right]^2 \approx \frac{1}{4T^2} \int_{\Lambda_{e-\delta t}}^\Lambda \frac{d^d-2q}{(2\pi)^{d-2}} \int_{-\infty}^\infty dq_z \frac{T^2}{2\pi |q|^2}, \]  

(D14)

as the main part of the contribution. We then have the second-order contribution from the random positional pinning as

\[ \delta R_0^{(2a)} (u) = A \left[ \frac{1}{2} R'^{(4)} (u) - R'^{(2)} (u) R''^{(2)} (0) \right] \delta \ell, \]  

(D15)

and

\[ \delta \Delta_f^{(2a)} (u) = -A_2 R'^{(4)} (u) \delta \ell. \]  

(D16)

For \( d = 3 \), we have

\[ A = \frac{\pi - 2}{8\pi^2 B^2 \lambda^3 \Lambda^3}, \]  

(D17)

\[ A_2 = \frac{\pi - 2}{16\pi^2 B^2 \lambda^5 \Lambda^5} = A/(2\Lambda^2). \]  

(D18)

The second order contribution of the random orientational pinning \( \Delta_f \) in (23) is

\[ -\frac{1}{2T} \left\langle H_3^2 \right\rangle >= -\frac{1}{32T^3} \sum_{\alpha_1, \beta_1, \alpha_2, \beta_2} \int_{x, z} \int_{x', z'} \left\langle \Delta_f \left[ u_{0i}^{0i}(x, z) - u_{0i}^{0i}(x, z) \right] \partial_x \left[ u_{02}^{02}(x, z) - u_{02}^{02}(x, z) \right] \delta x \right\rangle >= \]  

\[ \times \Delta_f \left[ u_{02}^{02}(x, z') - u_{02}^{02}(x, z') \right] \partial_x \left[ u_{02}^{02}(x', z') - u_{02}^{02}(x', z') \right] \delta x \right\rangle >, \]  

(D19)

which after separating the high and low wavevector components becomes

\[ \left\langle \Delta_f \left[ u_{0i}^{0i}(x, z) \right] \partial_x u_{0i}^{0i} \right\rangle^2 \Delta_f \left[ u_{02}^{02}(x, z) \right] \partial_x u_{02}^{02} \right\rangle > = \Delta_f \left[ u_{0i}^{0i}(x, z) \right] \Delta_f \left[ u_{02}^{02}(x, z) \right] \left\langle \left( \partial_x u_{0i}^{0i} \right)^2 \left( \partial_x u_{02}^{02} \right)^2 \right\rangle > \]  

\[ + 2 \Delta_f \left[ u_{0i}^{0i}(x, z) \right] \frac{\Delta''_{\alpha_2 \beta_2}}{2} \left( \partial_x u_{02}^{02} \right)^2 \left( \partial_x u_{02}^{02} \right)^2 \left( u_{0i}^{0i} \right)^2 \left( u_{0i}^{0i} \right)^2 > \]  

\[ + 4 \Delta_f \left[ u_{0i}^{0i}(x, z) \right] \partial_x u_{0i}^{0i} \partial_x u_{02}^{02} \left( \partial_x u_{0i}^{0i} \right)^2 \left( u_{02}^{02} \right)^2 + \cdots, \]  

(D20)

where for simplicity of notation we defined \( [u_{0i}^{0i}(x, z) - u_{0i}^{0i}(x, z)] = u_{0i}^{0i}(x, z) \). The average in the first term of (D20) is given by (neglecting the three replica contribution)
\[
\left\langle \left( \partial_x u_{0>0}^{\alpha_1,\beta_1} \right)^2 \left( \partial_x u_{0>0}^{\alpha_2,\beta_2} \right)^2 \right\rangle_c = 4 \left[ C_{T,\gamma}^> (\delta x, \delta z) \right]^2 \left( \delta_{\alpha_1,\alpha_2} \delta_{\beta_1,\beta_2} - 2 \delta_{\alpha_1,\beta_2} \delta_{\beta_1,\alpha_2} \right),
\]
\quad \text{(D21)}
\]

in which the correlation of the \(x\) derivative of the layer fluctuation, \(C_{T,\gamma}^>\), is
\[
C_{T,\gamma}^> (\delta x, \delta z) = \left\langle \partial_x u_{0>0} (x, z) \partial_x u (x + \delta x, z + \delta z) \right\rangle.
\quad \text{(D22)}
\]

Similarly to (D12), this term provides the second-order contribution as
\[
\delta R_{\gamma}^{(2b)} (u) = A_3 \left[ \frac{1}{2} \Delta_f (u) \Delta_f (u) - \Delta_f (u) \Delta_f (0) \right] \delta \ell,
\quad \text{(D23)}
\]
\[
\delta \Delta_f (2b) (u) = -A_4 \Delta_f (u) \Delta_f (u) \delta \ell,
\quad \text{(D24)}
\]

where
\[
A_3 \delta \ell = \frac{1}{2T^2} \int_{\delta x, \delta z} \left[ C_{T,\gamma}^> (\delta x, \delta z) \right]^2,
\quad \text{(D25)}
\]
and
\[
A_4 \delta \ell = \frac{1}{4T^2} \int_{\delta x, \delta z} (\delta x)^2 \left[ C_{T,\gamma}^> (\delta x, \delta z) \right]^2.
\quad \text{(D26)}
\]

The average in the second term of (D20) is
\[
\left\langle \left( \partial_x u_{0>0}^{\alpha_1,\beta_1} \right)^2 \left( u_{0>0}^{\alpha_2,\beta_2} \right)^2 \right\rangle_c = 4 \left[ C_{T,\gamma/2}^> (\delta x, \delta z) \right]^2 \left( \delta_{\alpha_1,\alpha_2} \delta_{\beta_1,\beta_2} - \delta_{\alpha_1,\beta_2} \delta_{\beta_1,\alpha_2} \right),
\quad \text{(D27)}
\]
where the correlation \(C_{T,\gamma/2}^>\) is defined through
\[
C_{T,\gamma/2}^> (\delta x, \delta z) = \left\langle u_{0>0} (x, z) \partial_x u (x + \delta x, z + \delta z) \right\rangle.
\quad \text{(D28)}
\]
It is easy to see that this term contributes to the random orientational pinning nonlinearity
\[
\delta \Delta_f (2c) = -A_5 \left[ \Delta_f (u) \Delta_f (u) - \Delta_f (u) \Delta_f (0) \right] \]
\[
- \Delta_f (0) \Delta_f (0),
\quad \text{(D29)}
\]
with
\[
A_5 = \frac{1}{2T^2} \int_{\delta x, \delta z} \left[ C_{T,\gamma/2}^> (\delta x, \delta z) \right]^2.
\quad \text{(D30)}
\]

The average in the third term of (D20) is
\[
\left\langle \left( \partial_x u_{0>0}^{\alpha_1,\beta_1} \partial_x u_{0>0}^{\alpha_2,\beta_2} \partial_x u_{0>0}^{\alpha_3,\beta_3} \right)^2 \right\rangle_c = 4 \left\{ C_{T}^> (\delta x, \delta z) C_{T}^> (\delta x, \delta z) + \left[ C_{T,\gamma/2}^> (\delta x, \delta z) \right]^2 \right\}
\times \left( \delta_{\alpha_1,\alpha_2} \delta_{\beta_1,\beta_2} - 2 \delta_{\alpha_1,\beta_2} \delta_{\beta_1,\alpha_2} \right),
\quad \text{(D31)}
\]
which contributes to the random orientational pinning nonlinearity through
\[
\delta \Delta_f (2d) (u) = -A_6 \left[ \frac{1}{2} \Delta_f (u) \Delta_f (u) - \Delta_f (u) \Delta_f (0) \right],
\quad \text{(D32)}
\]
with
\[
A_6 = \frac{4}{T^2} \int_{\delta x, \delta z} \left\{ C_{T}^> (\delta x, \delta z) C_{T}^> (\delta x, \delta z) + \left[ C_{T,\gamma/2}^> (\delta x, \delta z) \right]^2 \right\}.
\quad \text{(D33)}
\]

The contribution to the Hamiltonian from the cross term, the third term in (D20), is
\[
- \frac{1}{T} \left\langle H_{\Delta f} H_{\Delta x} \right\rangle_c = \frac{1}{8T^3} \sum_{\alpha_1,\beta_1,\alpha_2,\beta_2} \int_{x,z} \int_{x',z'} \left\langle \Delta_f \left[ u_{0>0}^{\alpha_1}(x, z) - u_{0>0}^{\beta_1}(x, z) \right] \partial_x \left[ u_{0>0}^{\alpha_1}(x, z) - u_{0>0}^{\beta_1}(x, z) \right] \right\rangle_c
\times \left[ u_{0>0}^{\alpha_2}(x', z') - u_{0>0}^{\beta_2}(x', z') \right] \left\rangle_c.
\quad \text{(D34)}
\]

Similarly, we can separate the long- and short-scale field and keep only the leading-order contribution, thus
\[ \langle \Delta_f \left[ u_0^{\alpha_1}(x, z) - u_0^{\beta_1}(x, z) \right] \partial_x \left[ u_0^{\alpha_1}(x, z) - u_0^{\beta_1}(x, z) \right] \rangle \]
\[ = \frac{1}{4} \Delta_f^c' \left( u_0^{\alpha_1 \beta_1} \right) R_v' \left( u_0^{\alpha_2 \beta_2} \right) \left( \partial_x u_0^{\alpha_1 \beta_1} \right)^2 \left( u_0^{\alpha_2 \beta_2} \right)^2 \]
\[ + \frac{1}{2} \Delta_f \left( u_0^{\alpha_1 \beta_1} \right) R_v' \left( u_0^{\alpha_2 \beta_2} \right) \left( \partial_x u_0^{\alpha_1 \beta_1} \right)^2 \left( u_0^{\alpha_2 \beta_2} \right)^2 \]
\[ + \ldots . \]

(D35)

The average in the first term of (D35) is easy to calculate as
\[ \langle \left( u_0^{\alpha_1 \beta_1} \right)^2 \left( u_0^{\alpha_2 \beta_2} \right)^2 \rangle^c \]
\[ = 4 \left[ C_0^c \left( \delta x, \delta z \right) \right]^2 \left( \delta \alpha_1 \delta \beta_1 \delta \beta_2 \delta \alpha_2 \right) \]
\[ - \delta \alpha_2 \delta \beta_1 \delta \beta_2 \delta \alpha_1 \beta_2, \]  
(D36)

and it contributes
\[ \delta \Delta_f^{(2e)}(u) = A \left[ \Delta_f^c' \left( u \right) R_v'(u) - \Delta_f^c'(0) \right] \delta \ell, \]  
(D37)

with constant \( A \) given in (D33).

The average in the second term of (D35) is
\[ \left( \partial_x u_0^{\alpha_1 \beta_1} \right)^2 \left( u_0^{\alpha_2 \beta_2} \right)^2 \chi \]
\[ = 4 \left[ C_0^c \left( \delta x, \delta z \right) \right]^2 \left( \delta \alpha_1 \delta \beta_1 \delta \beta_2 \delta \alpha_2 \right) \]
\[ - \delta \alpha_2 \delta \beta_1 \delta \beta_2 \delta \alpha_1 \beta_2, \]  
(D38)

and it contributes
\[ \delta R_v^{(2f)} = -A_0 \left[ \Delta_f(u) R_v'(u) - \Delta_f(0) R_v'(u) \right] \delta \ell, \]  
(D39)

with \( A_0 \) given in (D33).

These second- and lower-order contributions sum up into flow equations of the non linearities given as Eqs. (8) and (9) in Sec. V A.

Appendix E: Full behavior of long scale correlation function

The RG and matching analysis in Sec. IV predicts that the long-scale smectic phonon correlation is dominated by random orientational pinning, with strength \( \Delta_f(T) = \Delta_f \delta f(T) \). The correlation is given by
\[ C(x, z) = 2 \int dq_x dq_z \Delta_f(T) q_x^2 \sqrt{\frac{\lambda^2 q_x^2 + q_x^2}{\lambda^2 q_x^4 + q_x^4}} \times \left( 1 - e^{q_x x + q_x z} \right), \]  
(E1)

in which the integrations can be safely extended to infinity with our focus on long scale behavior. Given \( A \) as a positive number, it is easy to observe a relation whereby
\[ C(\sqrt{A}x, Az) = \sqrt{A}C(x, z), \]  
(E2)

which is consistent with the results shown in Eq. (7), and, on the \( x \) or \( z \) axis,
\[ C(x, 0) \propto x, \text{ and, } C(0, z) \propto \sqrt{z}. \]  
(E3)

The correlation thus can be characterized by
\[ C(x, z) \propto x f \left( \frac{\lambda z}{x^2} \right), \]  
(E4)

in which, at different limits of the ratio \( t = \lambda z/x^2 \),
\[ \begin{cases} f(t) = \text{const.}, & \text{for } t \to 0, \\ f(t) \propto \sqrt{t}, & \text{for } t \to \infty. \end{cases} \]  
(E5)

Redefining variables
\[ (u, v) = (x^2 q_x^2, z q_z), \]  
(E6)

so \( (q_x, q_z) = (\sqrt{u}/x, v/z) \), Eq. (E1) then becomes
\[ C(x, z) = \frac{\Delta_f(T)}{\pi^2 B^2 \lambda} \int_0^\infty dq_x \int_0^\infty dq_z \sqrt{\frac{\lambda^2 q_x^2 + q_x^2}{\lambda^2 q_x^4 + q_x^4}} \times \left[ 1 - \cos (q_x x) \cos (q_z z) \right] \]
\[ = \frac{\Delta_f(T)}{4 \pi^2 B^2 \lambda^3} \int_0^\infty dt^2 \int_0^\infty du \sqrt{u} \frac{\sqrt{t^2 u^2 + v^2} - tu}{v^2 (t^2 u^2 + v^2)} \times \left[ 1 - \cos (\sqrt{v}) \cos (v) \right] \]
\[ = \frac{\Delta_f(T)}{4 \pi^2 B^2 \lambda^3} \frac{\lambda}{x f(t)}, \]  
(E7)

with
\[ f(t) = 2t^2 \int_0^\infty dv \int_0^\infty du \sqrt{u} \frac{\sqrt{t^2 u^2 + v^2} - tu}{v^2 (t^2 u^2 + v^2)} \times \left[ 1 - \cos (\sqrt{v}) \cos (v) \right]. \]  
(E8)

Writing \( 1 - \cos (\sqrt{v}) \cos (v) \) as \( [1 - \cos (\sqrt{u})] + \cos (\sqrt{u}) [1 - \cos (v)] \), it is easy to obtain the full analytic expression and limits of \( f(t) \) as given in Eq. (10) and plotted in Fig. 7.

[35] Because here we are focusing on thermotropic smectics whose period a is comparable to quenched disorder correlation length ξo (both on the order of molecular scale ~10 nm), we neglected the (otherwise) intermediate random manifold regime [22–26]. In contrast in lyotropic (e.g. surfactant systems) we expect a ≪ ξo thereby allowing random manifold. We leave analysis of this more involved case to future study.

[45] This is unlikely to be a physically realizable regime because for weak pinning the penetration length into the bulk is expected to be much longer than the X-ray wavelength. This case requires numerical analysis that we leave for the future.
