Elevated body mass in National Football League players linked to cognitive impairment and decreased prefrontal cortex and temporal pole activity

K Willeumier, DV Taylor and DG Amen

Obesity is a risk factor for neurodegenerative disease and has been shown to adversely affect cognitive function. Professional athletes who participate in sports, which expose them to repetitive concussions, may be at heightened risk for cognitive impairment. Here, we investigated the effects of body mass as measured by waist-to-height ratio (WHtR) on regional cerebral blood flow using single-photon emission computed tomography imaging in 38 healthy weight (WHtR mean 49.34 ± 2.8; age 58 ± 9.6) and 38 overweight (WHtR mean 58.7 ± 4.7; age 58 ± 13.3) retired National Football League football players. After matching for age and position, we used a two sample t-test to determine the differences in blood flow in healthy versus overweight subjects. Statistical parametric mapping revealed a higher WHtR ratio is associated with decreased blood flow in Brodmann areas 8, 9 and 10, brain regions involved in attention, reasoning and executive function (P < 0.05, family-wise error) along with deficits in the temporal pole. Moreover, overweight athletes had significant decrease in attention (P = 0.01326), general cognitive proficiency (P = 0.012; Microcog: Assessment of Cognitive Functioning) and memory (P = 0.005; Mild Cognitive Impairment Screen). The association between elevated WHtR percentage and decreased blood flow in the prefrontal cortex and temporal pole may be correlated with the decreased performance on tests of attention and memory. These findings suggest that a weight management program may be critical to the health of athletes who have been exposed to mild brain trauma during their careers.

Translational Psychiatry (2012) 2, e68; doi:10.1038/tp.2011.67; published online 17 January 2012

Introduction

Obesity is a growing epidemic in youth,1 collegiate2 and professional football players,3 thus, potentially escalating the risk for cognitive impairment in a group that is already at risk due to repetitive subconcussive and concussive brain trauma. Recent studies have highlighted the impairments in executive cognitive function in overweight healthy adults,4 but no study to date has investigated the effects of weight on brain function in professional athletes. This is a unique population of strength-trained individuals who are required to have a higher body mass for competitive purposes. Body mass index was found not to be a valid indicator of overweight and obesity in a collegiate football population,5 suggesting that the waist-to-height ratio (WHtR) is a more appropriate assessment of the healthy weight of an amateur or professional athlete. We have observed that retired football players are susceptible to weight gain.6 Therefore, it is important to evaluate if the combination of weight gain and brain trauma in football players has an additive negative effect on brain function.

Using single-photon emission computed tomography (SPECT) imaging, we have previously demonstrated significant global decreases in blood flow in a study of 100 retired professional National Football League (NFL) football players.7 In addition, we recently found a decrease in blood flow in the prefrontal cortex of normal, healthy individuals who have an elevated body mass.8 On the basis of our previous findings, we hypothesized that similar blood flow deficits and cognitive deficits are present in a group of overweight athletes who have been exposed to repetitive subconcussive or concussive collisions as compared with normal-weight players.

To test our hypothesis, we measured regional cerebral blood flow (rCBF) in 38 normal-weight and 38 overweight retired NFL players who had previously visited our clinic to participate in a brain trauma study. We utilized SPECT imaging as a measure of blood flow, and we administered the Microcog: Assessment of Cognitive Functioning (MACF) and Mild Cognitive Impairment Screen (MCIS) to assess mental performance and attention. We hypothesized an inverse correlation between WHtR percentage and scores on attention, reasoning and general cognitive function in addition to significant deficits in blood flow in the prefrontal cortex.

Materials and methods

Subjects. We recruited a total of 100 active and retired players, representing 27 teams and all positions to participate in a study measuring the impact of playing professional American football on long-term brain function.
Continuous Performance Test II. The radiopharmaceutical normal lighting while they performed the Conner’s 99m HMPAO) intravenously. Subjects were injected in Technetium-99m hexamethylpropyleneamine oxime (Tc- resolution brain SPECT imaging to measure rCBF. Each participant was interviewed by a physician and completed a detailed history. Weight and height were obtained on all participants and a WHtR was calculated by dividing the waist circumference in inches by height in inches.

Neuropsychological exams. As part of the evaluation the MACF was administered. This exam measures the following nine parameters: general cognitive functioning, general cognitive proficiency, information processing speed, information processing accuracy, attention, reasoning, memory, spatial processing and reaction time. The MACF scores were compared with its own standardized sample (n = 810) chosen to be representative to the US population of adults with regard to education, gender and ethnicity between the ages of 18 and 89. Participants were also given the MCIS, a screening tool found to be reliable in distinguishing mild cognitive impairment from normal.

SPECT scans. In addition, each subject underwent high-resolution brain SPECT imaging to measure rCBF. Each subject received an age/weight-appropriate dose of Technetium-99m hexamethylpropyleneamine oxime (Tc-99m HMPAO) intravenously. Subjects were injected in normal lighting while they performed the Conner’s Continuous Performance Test II. The radiopharmaceutical was injected 3 min after starting the 15-min test. All subjects completed the task. Subjects were then scanned 30 min later using a high-resolution Picker Prism 3000 triple-headed gamma camera (Picker Int. Inc., Ohio Nuclear Medicine Division, Bedford Hills, OH, USA) with fan beam collimators, acquiring data in 128 × 128 matrices, yielding 120 images per scan with each image separated by 3° spanning 360°. SPECT data were processed and attenuation correction performed using general linear (Chang) methods. All images were reconstructed and resliced using an oblique reformatting program, according to anterior–posterior commissure line so that the final images were similarly aligned for analysis.

Table 1 Demographics

| Ethnicity              | N  |
|------------------------|----|
| African American       | 33 |
| Caucasian              | 60 |
| Hispanic               | 1  |
| Mixed                  | 6  |

| Positions (N = 100)   | N  |
|-----------------------|----|
| Quarterback           | 5  |
| Running back          | 8  |
| Wide Receivers        | 7  |
| Tight Ends            | 7  |
| Offensive lineman      | 26 |
| Defensive lineman      | 12 |
| Linebackers           | 17 |
| Defensive backs        | 18 |

(see Table 1 for demographics). Players were recruited from retired NFL Players Association meetings and by participants informing other players about the study. Of these 100 subjects, 76 were participants in this study, as we were able to attain their waist sizes. Each player met our inclusion criteria of being on an active NFL roster for a minimum of 3 years. We excluded subjects who could not cease taking psychoactive medications (recreational or otherwise) for an appropriate washout period before scanning. In all, 12% of the participants had a prior or current history of psychoactive medication use. All subjects received an explanation of the research study and gave written informed consent in accordance with an Institutional Review Board-approved protocol.

Evaluation. Each participant was interviewed by a physician and completed a detailed history. Weight and height were obtained on all participants and a WHIR was calculated by dividing the waist circumference in inches by height in inches.

_image analysis_. Differences in HMPAO uptake were analyzed using Statistical Parametric Mapping 8 software (Wellcome Department of Cognitive Neurology, London, UK) implemented on the Matlab platform (Math Works, Sherborn, MA, USA). Statistical parametric maps (SPMs) are spatially extended statistical processes that are constructed to test hypotheses about regionally specific effects in neuroimaging data. SPM combines the general linear model and the theory of Gaussian random fields to make statistical inferences about regional effects. The images were spatially normalized using a 12-parameter affine transformation followed by non-linear deformations to minimize the residual sum of squares between each scan and a reference or template image conforming to the standard space defined by the Montreal Neurological Institute template. The original image matrix obtained at 128 × 128 × 29 with voxel sizes of 2.16 × 2.16 × 6.48 mm were transformed and resliced to a 79 × 95 × 68 matrix with voxel sizes of 2 × 2 × 2 mm consistent with the Montreal Neurological Institute template. The normalized images were smoothed using an 8-mm full-width half maximum isotropic Gaussian kernel.

Statistical analysis. SPECT scans from age- and position-matched normal-weight players were compared with overweight retired NFL players using statistical parametric mapping (SPM) with t-contrast modeling. The linear relationship between WHIR and blood flow was evaluated using the SPM multiple regression model. The differences in general cognitive function, general cognitive proficiency, reasoning, attention and memory were evaluated using SPSS statistical software for Windows (SPSS, Chicago, IL, USA) and P < 0.05 was considered statistically significant.

Results

Elevated WHIR decreases cognitive performance and rCBF. Average WHIR in our overweight group was 58.7 ± 4.7 (range 53–72.97) and in our healthy weight group was 49.34 ± 2.8 (range 41.03–52.9) with the means being statistically different (t (274) = 10.473, P < 0.001). Those with a WHIR percentage under 53% were categorized as healthy weight. We matched players by age and position based on findings from our previous work with this NFL group which demonstrated a significant relationship between position and cognitive function.
Initially, we examined results of the general cognitive proficiency and the general cognitive function as an assessment of cognition in those with increased WHtR using the MACF. A between-group ANOVA demonstrated decreases in general cognitive proficiency (\(P = 0.017\)) and general cognitive function (\(P = 0.025\)) as a main effect. The decrease in general cognitive proficiency remained significant after Bonferroni correction for the two comparisons (\(P < 0.025\)). To discern which factors contributed to decreased general cognitive proficiency, we evaluated attention, memory, reasoning, information processing speed, and information processing accuracy between the two groups. These variables were previously demonstrated to be areas of deficit as well as sensitive to improvement in our previous study.\(^6\) Consistent with the decrease in general cognitive proficiency, information processing accuracy was significantly decreased (\(P = 0.024\)) but not information processing speed; general cognitive proficiency is more sensitive to processing accuracy than speed. Of the three underlying domains that contribute to an overall decrease in cognitive proficiency, we found decreases in reasoning (\(P = 0.023\)) and attention (\(P = 0.023\)) but not memory in those with elevated WHtR using the MCAF. An independent evaluation of memory function using the MCIS, which is sensitive to age-related memory impairment, revealed significant deficits with increased body mass (\(P = 0.003\)).

Our initial SPM analysis on brain SPECT concentration scans revealed global diffuse decreases in blood flow in the frontal, temporal and parietal lobes of subjects in the elevated WHtR group at \(P < 0.001\), uncorrected for family-wise error (FWE; Figure 1). We then refined our analysis to include regions associated with focus, impulsivity and attention (Brodmann areas 8, 9, 10, 11 and 44) based on previous data demonstrating elevated body mass index results in decreased executive function\(^4,13\) metabolic activity\(^14\) and blood flow\(^5\) in the prefrontal cortex. This analysis emphasized the regions of significant decreases were specific to Brodmann areas 8, 9 and 10 in the elevated WHtR group at \(P < 0.05\) FWE. Figure 2 illustrates the three-dimensional cortical representation of these brain regions and Table 2 provides the regional areas of significant decrease with the largest cluster size as identified through SPM and defined by the Automated Anatomical Labeling Atlas. These areas include the left and right superior and middle frontal gyri. No significant increases were observed.

**Figure 1** Three-dimensional surface images showing global regions of decreased perfusion in the elevated WHtR cohort at \(P < 0.001\) (uncorrected). Cortical surface views showing significant hypoperfusion in NFL players with elevated WHtR \((n = 38)\) compared with those who have a normal WHtR \((n = 38)\). Regions showing the most hypoperfusion include the bilateral frontal, temporal and parietal lobes, and cerebellum. The statistical threshold was set at \(P < 0.001\). Significant decreases are in blue. No increases were observed.

**Figure 2** Three-dimensional surface images showing areas of decreased perfusion in the prefrontal cortex with elevated WHtR at \(P < 0.05\). Cortical surface views demonstrate decreased regional cerebral blood flow in Brodmann areas 8, 9, 10 in players with a high WHtR at \(P < 0.05\), family-wise error (FWE). Significant decreases are in blue. No increases were observed.

As body mass increases frontal and temporal lobe perfusion decreases. Linear regression analysis at \(P < 0.001\) FWE measuring the effect of WHtR on blood flow while controlling for age, predicts the most significant decreases as reported by voxel cluster size in the following five regions: Region 1 has an overall cluster size of 2666 voxels and includes the left superior temporal pole (coordinates \(-40, 16, -20\); \(t = 6.91\)), left frontal medial orbital cortex (coordinates \(-2, 30, -14\); \(t = 6.79\)) and left insular cortex (coordinates \(-28, 18, -16\); and \(t = 6.78\)). Region 2 has an overall cluster size of 207 voxels and includes the left frontal medial orbital cortex (coordinates \(-8, 56, -14\); \(t = 6.35\)) and right rectus (coordinates 8, 56, -18; \(t = 6.35\)). Region 3 has an overall cluster size of 342 voxels and includes the right superior temporal pole (coordinates 48, 10, -14; \(t = 6.23\) and coordinates 32, 12, -32; \(t = 7.10\)). Region 4 has an overall cluster size of 253 voxels at the left middle frontal cortex (coordinates -32, 54, 20; \(t = 6.22\)). Region 5 has an overall cluster size of 90 voxels and includes the frontal superior right cortex (coordinates 14, -42, 52; \(t = 6.17\) and coordinates 18, 54, 42; \(t = 5.96\)). Figure 3...
illustrates these decreased areas of perfusion through transverse, coronal and sagittal slices. Furthermore, a plot of the regression slope of region 1 (left superior temporal pole and left frontal medial orbital cortex) demonstrates a negative correlation between WHtR and blood flow at $P < 0.001$ FWE (Figures 4 and 5). This suggests that as body mass increases, the blood flow to both temporal pole and prefrontal cortex decreases.

Discussion

Obesity is a worldwide epidemic and is becoming an issue of concern in certain contact sports like football.\textsuperscript{1,3,5,15} Previously, we have demonstrated significant global decreases in blood flow in a population of retired NFL players compared with healthy subjects,\textsuperscript{7} and we have observed decreases in blood flow to the prefrontal cortex in a group of healthy, cognitively normal individuals who were overweight.\textsuperscript{8} Here, we show that retired, overweight NFL players have significantly more decreases in blood flow in the prefrontal cortex and temporal pole, and greater cognitive impairment than those retired NFL players categorized as normal weight. It appears that both playing professional football and being

Obesity has been linked to executive dysfunction, and our cohort of overweight NFL players demonstrate decreased performance in the areas of attention and cognitive functioning upon neuropsychological evaluation. These observations may correlate with the decrements in metabolic activity to the prefrontal cortex and temporal pole that we observe in our overweight athletes. Alternatively, the cognitive deficits may be attributed to the elevated circulation of pro-inflammatory cytokines (C-reactive protein, tumor necrosis factor α or interleukin-6) with a corresponding decrease in beneficial adipokines, triggering a cascade of apoptosis, neuroinflammation, microglia activation and blood–brain barrier damage often observed with metabolic syndrome. Brain imaging studies have reported the deleterious effects of having a high body mass index being associated with lower brain volume and impaired frontal lobe function. Therefore, it is clear that obesity has a role in compromised brain function, and we report here that retired NFL players who are overweight have greater cognitive impairment and blood flow deficits in the prefrontal cortex and temporal pole as compared with their normal-weight cohorts.

Obesity has been linked to executive dysfunction, and our cohort of overweight NFL players demonstrate decreased performance in the areas of attention and cognitive functioning upon neuropsychological evaluation. These observations may correlate with the decrements in metabolic activity to the prefrontal cortex and temporal pole that we observe in our overweight athletes. Alternatively, the cognitive deficits may be attributed to the elevated circulation of pro-inflammatory cytokines and biomarkers that result in myelin abnormalities, which have been documented in the frontal lobes of obese individuals. With the heightened prevalence of obesity and cardiovascular disease risk factors in NFL players, our results suggest this trend will have negative, long-term consequences on brain health and may lead to complications due to stroke or chronic traumatic encephalopathy. If this finding is replicated it indicates that proper weight education and management may be essential to the future health of athletes who have been exposed to repetitive brain trauma.
