Abstract

The difficulty in analyzing LSTM-like recurrent neural networks lies in the complex structure of the recurrent unit, which induces highly complex nonlinear dynamics. In this paper, we design a new simple recurrent unit, which we call Prototypical Recurrent Unit (PRU). We verify experimentally that PRU performs comparably to LSTM and GRU. This potentially enables PRU to be a prototypical example for analytic study of LSTM-like recurrent networks. Along these experiments, the memorization capability of LSTM-like networks is also studied and some insights are obtained.

Introduction

Deep learning has demonstrated great power in the recent years and appears to have prevailed in a broad spectrum of application domains (see, e.g., \cite{12, 17}). Despite its great successes, the effectiveness of deep neural networks has not been understood at a theoretical depth. Thus developing novel analytic tools and theoretical frameworks for studying deep neural networks is of the greatest importance at the present time, and is anticipated to be a central subject of machine learning research in the years to come.

This work is motivated by the thrust of understanding recurrent neural networks, particularly LSTM/GRU-like networks \cite{4, 8, 9, 13, 23}. These networks have demonstrated to be the state-of-the-art models for time series or sequence data \cite{1, 10, 21}. Recently LSTM/GRU recurrent units have also been successfully adopted for modelling other forms of data (e.g., \cite{3, 22}). Despite these successes, the design of LSTM and GRU recurrent units was in fact heuristical; to date there is little theoretical analysis justifying their effectiveness. A particularly interesting observation regarding these networks is that they appear to possess “long-term memory”, namely, being able to selectively “remember” the information from many time steps ago \cite{7}. As one may naturally expect such memorization capability to have played an important role in the working of these networks, this aspect has not been well studied, analytically or experimentally.

The difficulty in analyzing recurrent networks resides in the complex structure of the recurrent unit, which induces highly complex nonlinear dynamics. To understand LSTM-like recurrent networks, the methodology explored in this theme of research is
to maximally simplify the structure of the recurrent unit. That is, we wish to construct
an alternative recurrent unit that captures the key components LSTM and GRU but
stays as simple as possible. Such a unit can then be used for the study of recurrent
networks and its structural simplicity may allow easier analysis in future research.

Towards that goal, the main objective of this present paper is to design such a
recurrent unit and verify that this unit performs comparably to LSTM and GRU. To that
end, we develop a new recurrent unit, which we call the Prototypical Recurrent Unit
(PRU). We rationalize our design methodology from a system-theoretic perspective
where a recurrent unit is understood as a causal time-invariant system in state-space
representations. Insights from previous research suggest that additive evolution appear
essential for LSTM-like networks to avoid the “gradient-vanishing” problem under
back-propagation [5,14,18]. This understanding is also exploited in our design of PRU.

The performance of PRU is verified and compared against LSTM and GRU via exten-
sive experiments. Using these three kinds of recurrent unit, we not only experiment
on constructing a standard language model for character prediction [19], but also test
the recurrent units for two controlled learning tasks, the Adding Problem [13], and the
Memorization Problem. The latter problem is what we propose in this work specifically
for studying the memorization capability of the recurrent networks. All experimental
results confirm that PRU performs comparably to LSTM and GRU, achieving the pur-
pose of this paper.

As another contribution, our experiments in this work demonstrate that the intrinsic
memorization capability of the recurrent units depends critically on the dimension of
the state space. The amount of targeted information (for memorization), the duration
of memory, and the intensity of the interfering signal also directly impact the memo-

Finally it is perhaps worth noting that although PRU is designed to be a prototype
which hopefully allows for easier analysis in future research, our experiments suggest
that it can also be used as a practical alternative to LSTM and GRU. A particular ad-

vantange of PRU is its time complexity. In this metric, PRU demonstrates to be superior
to both LSTM and GRU.

State-Space Representations

In system theory [15], a (discrete-time) system can be understood as any physical or
conceptual device that responds to an input sequence \( x_1, x_2, \ldots \) and generates an
output sequence \( y_1, y_2, \ldots \), where the indices of the sequences are discrete time. In general,
each \( x_t \) and each \( y_t \) at any time \( t \) may be a vector of arbitrary dimensions. We
will then use \( \mathcal{X} \) and \( \mathcal{Y} \) to denote the vector spaces from which \( x_t \) and \( y_t \) take value
respectively. We will call \( \mathcal{X} \) the input space and \( \mathcal{Y} \) the output space. The behaviour of
the system is characterized by a function \( J \) that maps the space of all input sequences
to the space of all output sequences. Then two systems \( J \) and \( J' \) are equivalent if \( J \) and
\( J' \) are identical as functions.

The class of systems that are of primary interest are causal systems, namely those
in which the output \( y_t \) at each time \( t \) is independent of all future inputs \( x_{t+1}, x_{t+2}, \ldots \).
The grand idea in system theory is arguably the introduction of the notion of state to
causal systems [15]. This makes state-space models the central topic in system theory, resulting in wide and profound impact on system analysis and design. In a nutshell, the state configuration is an quantity internal to the system, serving as a complete summary of the all past inputs so that given the current state, the current and future outputs are independent of all past inputs.

In this perspective, a recurrent unit can be regarded precisely as a causal time-invariant system in a state-space representation. We now formalize such a state-space representations.

At each time instant $t$, in addition to the input variable $x_t$ and output variable $y_t$, the representation of a recurrent unit also contains a state variable $s_t$, taking values in a vector space $S$, which will be referred to as the state space. Before the system is excited by the input, or at time $t = 0$, it is assumed that the state variable $s_0$ takes certain initial configuration, which is assumed customarily to be the origin $0 \in S$.

The behavior of the recurrent unit is governed by two functions $F : \mathcal{X} \times \mathcal{S} \rightarrow \mathcal{S}$ and $G : \mathcal{X} \times \mathcal{S} \rightarrow \mathcal{Y}$ as follows. At each time instant $t$, function $F$ maps the current input $x_t$ and the previous state $s_{t-1}$ to the current state $s_t$, namely, via

\[ s_t = F(x_t, s_{t-1}), \quad (1) \]

and function $G$ maps the current input $x_t$ and the current state $s_t$ to the current output $y_t$, namely, via

\[ y_t = G(x_t, s_t). \quad (2) \]
That is, in general a recurrent unit can be specified by the tuple \((X, Y, S, F, G)\) according to (1) and (2). We call such specification of the recurrent unit Type-I state-space representation of the unit, and denote it by \((X, Y, S, F, G)_{I}\).

As a clarification which might be necessary for the remainder of this paper, we pause to remark that in this paper (and under a system-theoretic perspective), the notion of a recurrent unit and that of a recurrent (neural) network are synonyms. In particular, a recurrent unit that operates over \(n\) time instances may be viewed as \(n\) copies of the same recurrent unit connected in a chain-structured network as shown in Figure 1 (top). In this “time-unfolded” view, the dependency structure between the variables in Type-I representation is shown in Figure 1 (middle).

It is remarkable that Type-I state-space representation is generic for any causal time-invariant system and hence generic for any recurrent unit. It is easy to verify that the recurrent unit in RNN [6], LSTM and GRU networks can all be expressed this way.

Since we aim at designing a simpler recurrent unit, we now introduce another simpler representation, which we call Type-II state-space representation. This representation is identical to the Type-I representation except that the function \(G\) is made to have domain \(S\), or alternatively put, the current output \(y_t\) at each time \(t\) is made dependent only of the current state \(s_t\). That is, \(G\) acts only on \(s_t\) and generates \(y_t\) via

\[
y_t = G(s_t).
\]

Under this representation, the recurrent unit is specified again by the tuple \((X, Y, S, F, G)\), but according to (1) and (3). We denote this representation by \((X, Y, S, F, G)_{II}\). A diagram exhibiting the dependency structure of the variables in this representation is shown in Figure 1 (bottom).

The following lemma suggests that Type-II representation has precisely the same expressive power as Type-I representation.

**Lemma 1** Given its input and output spaces \(X\) and \(Y\), a recurrent unit can be represented by \((X, Y, S, F, G)_{I}\) for some choice of \(S, F\) and \(G\) if and only if it can be represented by \((X, Y, \tilde{S}, f, g)_{II}\) for some choice of \(\tilde{S}, f\) and \(g\).

We now sketch the proof of this lemma.

The “if” part of the proof is trivial, since function \(G\) in Equation (3) is a special case of function \(G\) in Equation (2). The “only if” part can be proved by construction, proceeded as follows. Let \((X, Y, S, F, G)_{I}\) be given. Define \(\tilde{S} := X \times S\). Let function \(f : X \times \tilde{S} \to S\) be defined as follows: for each \((x, x', s) \in X \times X \times S = X \times \tilde{S}\), \(f(x, x', s) = (x^*, s^*) \in X \times S = \tilde{S}\), where \(x^* = 0 \in X\) and \(s^* = F(x, s) \in S\). Define function \(g : \tilde{S} \to Y\) as follows: for each \((x, s) \in X \times S = \tilde{S}\), \(g(x, s) = G(x, s)\). Now the lemma can be proved by identifying that systems \((X, Y, S, F, G)_{I}\) and \((X, Y, \tilde{S}, f, g)_{II}\) are equivalent. This latter fact can be easily established using proof by induction.

The significance of this lemma is that every recurrent unit can be represented using Type-II representation, in which the current output is made only dependent of the current state. In the proof of this result, we see that to convert a Type-I representation to a Type-II representation, it may require *increasing the dimension of the state space*. In
the worst case, although often unnecessary in practice, one can make the state space $\tilde{S}$ equal to the cartesian product $\mathcal{X} \times \mathcal{S}$ of the input space $\mathcal{X}$ and the state space $\mathcal{S}$ in the Type-I representation.

**Prototypical Recurrent Unit (PRU)**

Given that there is no loss of expressive power in Type-II representation, to arrive at a simplified recurrent unit, we will stay within this representation. That is, for some given choices of vector spaces $\mathcal{X}, \mathcal{Y},$ and $\mathcal{S}$, we will design two functions $F : \mathcal{X} \times \mathcal{S} \rightarrow \mathcal{S}$ and $G : \mathcal{S} \rightarrow \mathcal{S}$ for $(\mathcal{X}, \mathcal{Y}, \mathcal{S}, F,G)_1$. It is our hope that the designed recurrent unit captures the essence of recurrent unit in LSTM and GRU networks, but stays as simple as possible.

From the previous literature [20], the following properties of LSTM and GRU appear crucial for their effectiveness.

1. The recurrent unit behaves according to a nonlinear system, where the nonlinearity is induced by the use of nonlinear activation functions such as sigmoid, tanh, or ReLU functions.

2. The evolution from state $s_t$ to state $s_{t+1}$ is additive. It has been understood that such a property is critical for eliminating the problem of vanishing or blowing-up gradient in backpropagation.

Based on this understanding, our design philosophy is to impose these two properties *minimally* on the recurrent unit. Our hypothesis is that if these two properties are indeed essential, the resulting recurrent unit will behave in a way similar to GRU and LSTM recurrent units and can be used as a prototypical example for in-depth understanding of LSTM/GRU-like recurrent networks.

Such a design philosophy naturally results in the following new recurrent unit, which we call the Prototypical Recurrent Unit (PRU) and now describe.

We begin with some notations. We consider $\mathcal{X} = \mathbb{R}^m$, $\mathcal{Y} = \mathbb{R}^l$ and $\mathcal{S} = \mathbb{R}^k$; all vectors are taken as column vectors; the sigmoid (logistic or soft-max) function will be denoted by $\sigma$; when an activation function ($\sigma$, tanh, or any other function $h : \mathbb{R} \rightarrow \mathbb{R}$) applies to a vector, it acts on the vector element-wise and outputs a vector of the same length.

With these notations, we describe the functions $F$ and $G$ in $(\mathcal{X}, \mathcal{Y}, \mathcal{S}, F,G)_1$ that defines PRU.

**Function $F$:** The function $F$ is defined by the following sequence of function compositions involving two other variables $u_t \in \mathcal{S}$ and $c_t \in \mathbb{R}^k$ (we note that although here $c_t$ is a $k$-dimensional vector, it should not be interpreted as a state configuration in $\mathcal{S}$ due to its physical meaning).

$$ u_t = \tanh \left( U_s s_{t-1} + U_x x_t + b_u \right) \quad (4) $$

where $U_s$ is a $k \times k$ matrix, $U_x$ is a $k \times m$ matrix, and $b_u$ is a $k$-dimensional vector.

$$ c_t = \sigma \left( C_s^T s_{t-1} + C_x^T x_t + b_c \right) \quad (5) $$
where $C_s$ is a $k \times k$ matrix, $C_x$ is a $k \times m$ matrix, and $b_c$ is a $k$-dimensional vector.

$$s_t = c_t \odot s_{t-1} + (1 - c_t) \odot u_t$$  \hfill (6)

where $\odot$ is the element-wise product.

**Function $G$:** The function $G$ is defined as follows.

$$y_t = h(Ws_t + b)$$  \hfill (7)

where $W$ is an $l \times k$ matrix, $b$ is a length $l$ vector, and $h$ is an activation function. Depending on the applications and the physical meaning of output $y_t$, $h$ can be chosen as $\sigma$, tanh, ReLU, or even the identity function.

At this point, we have completely defined PRU, which is parameterized by $\theta := (C_x, C_s, b_c, U_x, U_s, b_u, W, b)$.

### Experimental Study

Our experimental study serves two purposes.

First, we wish to verify that the designed PRU behaves similarly as LSTM and GRU. For this purpose, experiments need to be performed not only for real-world applications, in which one has no control over the datasets, but also for certain meaningful tasks where we have full control over the data. Such controllable tasks will allow a comparison of these recurrent units over arbitrary ranges of data parameter settings, so as to fully demonstrate the performances of the compared recurrent units and reduce the risk of being biased by the statistics of a particular dataset.

Second, we wish to take the opportunity to investigate a fundamental aspect of recurrent networks, namely, their memorization capabilities. It has been experimentally observed and intuitively justified that LSTM/GRU-like recurrent unit has “long-term memory” [11]. Motivated by such observations, we are interested in thoroughly studying the memorization capability of these recurrent units and understand what factors may influence their memorization performance.

As such, we consider three different learning tasks, where the recurrent networks are trained to solve three different problems: the Memorization Problem, the Adding Problem, and the Character Prediction Problem. The Character Prediction Problem is a well-known problem in the real-world application domain [19] [16]. The Adding Problem is a controllable task, first introduced in [13]. The Memorization Problem is also a controllable task that we introduce in this work, inspired by the idea of a similar task presented in [2].

All models in these experiments have the architecture shown in the top diagram of Figure 1. In the description of the experiments, when we speak of “state space dimension”, for both PRU and GRU, it refers to the length of the vector passed between two consecutive recurrent units in the diagram. In LSTM networks, there are two vectors of the same length passed between two consecutive recurrent units. Although from a system-theoretic perspective, two times this length should be regarded as the state space dimension, this choice would put LSTM in disadvantage. This is because the output of
the unit depends only on one of the vectors. For this reason, for LSTM networks, the term “state space dimension” refers to half of the true state-space dimension.

Experiments on Memorization Problem and Adding Problem are performed on the computer (Intel(R) Core(TM) i5-4570 CPU @3.20Hz), whereas experiment on Character Prediction Problem is performed on a GeForce GTX 970 GPU. Time cost is evaluated in unit of second.

Memorization Problem

To describe this problem, let us first imagine a “memorization machine” \( \mathcal{M}_{\text{mem}} \) that behaves as follows. For any given non-negative integers \( I \) and \( N \), an input sequence \( x_1, x_2, \ldots, x_{I+N} \) of scalar values are fed to the machine, where for \( t = 1, 2, \ldots, I \), \( x_t \) takes on value in \( \{+1, -1\} \) each with probability \( \frac{1}{2} \), and for \( t = I + 1, I + 2, \ldots, I + N \), \( x_t \) is drawn independently from a Gaussian distribution with zero mean and variance \( \delta^2 \). After processing the input sequence, the machine generates an output vector \( (x_1, x_2, \ldots, x_I)^T \) of dimension \( I \). That is, as a function, the machine \( \mathcal{M}_{\text{mem}} \) behaves according to

\[
\mathcal{M}_{\text{mem}}(x_1, x_2, \ldots, x_{I+N}) = (x_1, x_2, \ldots, x_I)^T.
\]

Then in the Memorization Problem, the objective is to train a model that simulates the behaviour of \( \mathcal{M}_{\text{mem}} \), namely, capable of “memorizing” the “\( I \) bit” “targeted information” in the beginning of the input sequence, after \( N \) symbols of “noise” or “interfering signal” enter the model. Obviously, the Memorization Problem is configured by three parameters: \( I \), \( N \), and \( \delta \), where \( I \) represents the amount of targeted information, \( N \) represents the duration of memory, and \( \delta \) represents the intensity of noise that might interfere with the memorization behaviour of the model.

Modelling: Under a recurrent network model, it is natural to regard the input space \( \mathcal{X} \) as \( \mathbb{R}^I \) and the output space \( \mathcal{Y} \) as \( \mathbb{R}^I \), and one may freely configure the dimension \( k \) of the state space \( S \). Except at the final time \( t = I + N \), the output \( y_t \) is discarded, and final output \( y_{I+N} \) is used to simulate the output \( \mathcal{M}_{\text{mem}}(x_1, x_2, \ldots, x_{I+N}) \) of the memorization machine.

Datasets: For each problem setting \( (I, N, \delta^2) \), we generate 2000 training examples and 400 testing examples according to the specification of the problem.

Training: The training of each model is performed by optimizing the Mean Square Error (MSE) defined as

\[
\mathcal{E}_{\text{MSE}}(\theta) := \mathbb{E} \| \mathcal{M}_{\text{mem}}(x_1, x_2, \ldots, x_{I+N}) - y_{I+N} \|^2
\]

where the expectation operation \( \mathbb{E} \) is taken as averaging over the training examples. Mini-batched Stochastic Gradient Descent (SGD, in fact more precisely, mini-batched Back-Propagation Through Time) is used for this optimization. The batch size is chosen as 100, the learning rate as \( 10^{-3} \), and the number of epochs as 1000. Each component of the model parameters is initialized to random values drawn independently from the zero-mean unit-variance Gaussian distribution.

Evaluation Metrics: A trained model is evaluated using MSE defined in (8), where the expectation operation \( \mathbb{E} \) is taken as averaging over the testing examples. For experiment setting \( (I, N, \delta^2, k) \), each studied model is trained 50 times with different

Figure 2: MSE comparison of LSTM, GRU and PRU networks in Memorization Problem

random initializations, and the average MSE is taken the performance metric for the experiment setting. Time complexity for the three models are also evaluated.

**Results:** Results are obtained for LTSM, GRU and PRU under various problems settings (I, N, δ^2) and model state-space dimensions k.

Figure 2 shows the performance comparison of the three recurrent units. In this figure (and as well in Figures 3 and 4), it can be seen that the three units perform similarly, among which GRU’s performance is superior to the other two, and PRU outperforms LSTM to a certain extent. It can also be observed that with respect to any given parameter, the performance trends of the three units are identical.

Figure 3 shows how the performance of each unit is related to the problem parameters I, N, and δ^2. For every unit and a fixed state space dimension k, the following performance trend can be observed.

- The performance degrades with increasing I. That is, when the amount of targeted information increases, it becomes more difficult for the unit to memorize this information.

- The performance degrades with increasing N. That is, over a long period of time, the units tend to forget the targeted information.

- The performance degrades with increasing δ^2. That is, when the interfering signal become stronger, it is more difficult to memorize the targeted information.

Figure 4 shows how the performance of each unit varies with the state space dimension k. It is apparent from the figure that as the dimension of state space increases, the performance of each unit improves. This behaviour is sensible, since the role of the state variable in a recurrent unit may be intuitively understood as the “container” for “storing” information, and large state space would result in larger “storage capacity”.

From the table below (measured at k = 3 and I = 2), it can be observed that PRU has lowest time complexity, significantly below GRU and LSTM. This is a direct consequence of PRU’s structural simplicity.
Adding Problem

To describe the Adding Problem, let \( \mathcal{M}_{\text{add}} \) be an “adding machine”, which is a function mapping a length-\( N \) sequence \((x_1, x_2, \ldots, x_N)\) to a real number. In particular, each \( x_t \), \( t = 1, 2, \ldots, N \), is a vector in \( \mathbb{R}^2 \), and we may write \( x_t \) as \((x_t[1], x_t[2])^T\). At each \( t \), \( x_t[1] \) is a random value drawn independently from the zero-mean Gaussian distribution with variance \( \delta^2 \); and in the sequence \((x_1[2], x_2[2], \ldots, x_N[2])\), there are exactly two 1’s, the locations of which are randomly assigned; the remaining values of the sequence all are equal to 0. The behaviour of the adding machine is given by

\[
\mathcal{M}_{\text{add}}(x_1, x_2, \ldots, x_N) := \sum_{t=1}^{N} x_t[1] \cdot x_t[2].
\]

The objective of the Adding Problem is then to train a model that simulates the behaviour of \( \mathcal{M}_{\text{add}} \). Obviously, the Adding Problem is parametrized by the pair \((N, \delta^2)\). Intuitively, the Adding Problem demands higher “memorization capacity” than the Memorization Problem, since only counting the locations of the two 1’s in the second component the input sequence, there are \( \binom{N}{2} \) possibilities.

Adding Problem (k=2, δ^2=1)

Adding Problem (k=3, δ^2=1)

Figure 5: MSE comparison of LSTM, GRU and PRU in Adding Problem.

Modelling: Under a recurrent network model, it is natural to take input space \( \mathcal{X} = \mathbb{R}^2 \) and output space \( \mathcal{Y} = \mathbb{R} \). Except at the final time \( t = N \), the output \( y_t \) is discarded, and final output \( y_N \) is used to simulate the output \( M_{\text{add}}(x_1, x_2, \ldots, x_N) \) of the adding machine.

Datasets: For each problem setting \((N, \delta^2)\), we generate 2000 training examples and 400 testing examples according to the specification of the problem.

Training: The training of each model is performed by optimizing the MSE between the \( y_N \) and \( M_{\text{add}}(x_1, x_2, \ldots, x_N) \). A mini-batched SGD method is used for optimization, where we use the same set of training parameters as those in the Memorization Problem, except that the batch size is chosen as 50.

Evaluation Metrics: MSE is used as the evaluation metric, and the same averaging process as that for the Memorization Problem is applied.

Results: Figure 5 shows the performance comparison of LSTM, GRU and PRU in...
the Adding Problem, and Figure 6 shows the performance trend of each of the three units with respect varying parameters. Similar to the Memorization Problem, overall the three units perform comparably, with GRU superior to the other two units. It is worth noting in Figure 5 with low state-space dimension \((k = 1)\), PRU appears underperform LSTM. But as the state-space dimension increases, PRU catches up (at \(k = 2\)) and even out-performs LSTM (at \(k = 3\)). This may be explained as follows. First the Adding Problem demands higher “memorization capacity”. But as we discussed earlier, PRU uses the Type-II representation, which may need larger state-space for the same representation power.

These results also suggest that the three studied units all have identical performance trends with respect to state-space dimension or any given problem parameter. Conclusions similar to those in the Memorization Problem may be obtained. The time complexity of PRU is also the lowest among the three for the Adding Problem (table below, measured at \(k = 3\)).

| \(N\) | 2   | 4   | 6   | 8   | 10  |
|------|-----|-----|-----|-----|-----|
| LSTM | 0.4678 | 0.8097 | 1.1826 | 1.5450 | 2.0387 |
| GRU  | 0.4346 | 0.7270 | 0.9954 | 1.3106 | 1.5756 |
| PRU  | 0.3191 | 0.5822 | 0.7367 | 0.9380 | 1.2037 |

Character Prediction Problem

Let \(\mathcal{M}_{\text{char}}\) be a “character-prediction machine”, which takes an input sequence \((x_1, x_2, \ldots, x_N)\) of arbitrary length \(N\) and produces an output sequence of the same length. The input sequence is fed to the machine one symbol per time unit, and at each time \(t\), the machine is characterized by a function \(\mathcal{M}_{\text{char}}^t\) defined by

\[
\mathcal{M}_{\text{char}}^t(x_1, \ldots, x_t) := x_{t+1}.
\]

That is, for every input sequence, the output of the machine is the input sequence shifted in time. Here each symbol \(x^i\) is a character in a \(K\)-character alphabet. Each character in
the alphabet is represented by a length-$K$ one-hot vector. The objective of the Character Prediction Problem is then to train a model that simulates the behaviour of $M_{\text{char}}$.

**Modelling:** Naturally, both $X$ and $Y$ are taken as $\mathbb{R}^K$ in the models. The output $y_t$ is computed by a soft-max classifier.

**Dataset:** A Shakespeare drama dataset is used in this experiment, where each sentence is taken as an input sequence. The dataset consists of 1,115,393 occurrences of characters from an alphabet of size 64, where 90% of the sentences are used for training set and the rest is held out for testing.

**Training and Evaluation:** The objective of this problem is to minimize the (expected) cross entropy loss (CEL)

$$E_{\text{CEL}}(\theta) = -\mathbb{E} \left( \frac{1}{N} \sum_{t=1}^{N} \sum_{i=1}^{K} M_{\text{char}}^t(x_1, \ldots, x_t)[i] \log y_t[i] \right)$$

where we have used $v[i]$ to denote the $i$th component of vector $v$, and used $N$ to denote the length of the input sequence. Mini-batched SGD with Adadelta dynamic learning rate is used for optimization. All parameters are randomly initialized in $[-0.1, 0.1]$, and the base learning rate is set to 0.8. CEL is used to evaluate the models.

**Results:** Figure 7 plots the performances of the three units as functions of SGD epoch number. The three units show very close performances for the chosen three settings of state space dimension. The table below lists the CEL performance of the three recurrent units at the end of SGD iterations, where PRU appears slightly outperform the other two.

| State Space Dimension | LSTM | GRU  | PRU  |
|-----------------------|------|------|------|
| 64                    | 1.2752 | 1.3015 | 1.2245 |
| 96                    | 1.2211 | 1.2132 | 1.1894 |
| 128                   | 1.1584 | 1.1968 | 1.1410 |

The average training time for PRU, GRU, and LSTM per epoch are respectively 83.65, 104.65 and 188.86 seconds respectively, with PRU leading by a significant margin.

**Concluding Remarks**

This paper presents a new recurrent unit, PRU. Having very simple structure, PRU is shown to perform similarly to LSTM and GRU. This potentially allows the use of [1]https://github.com/karpathy/char-rnn
PRU as a prototypical example for analytic study of LSTM-like recurrent networks. Its complexity advantage may also make it a practical alternative to LSTM and GRU.

This work is only the beginning of a journey towards understanding recurrent networks. It is our hope that PRU may provide some convenience to this important endeavor.
