I. INTRODUCTION

In recent years, accelerator-based neutrino oscillation experiments in the United States have been designed to use Liquid Argon Time Projection Chambers (LArTPCs) as their central neutrino detection technology [1]. Charged particles that traverse these detectors ionize the noble liquid. The electrons so produced are drifted in a uniform electric field towards a readout plane. The location of the electrons collected on the anode, combined with their arrival time, offers mm-scale resolution images of charged particle interactions [2]. This level of tracking precision – coupled to the detailed calorimetric information that a totally active detector provides – is believed to be the key to resolving some of the ambiguities observed in previous experiments and to extending their energy reach to probe the MeV-scale physics sector [3, 4].

The Short Baseline Neutrino Program (SBN) [5] aims to clarify an anomalous signal observed by the Mini-BooNE experiment [6]. It will eventually make use of three LArTPCs of varying sizes: the Short Baseline Near Detector (SBND, 112 t), MicroBooNE (90 t) [7] and ICARUS (600 t) [8]. The DUNE experiment [9] is a project that will use the LArTPC technology to measure long-baseline neutrino oscillations with unprecedented precision. It will consist of a near detector (105 t) and a far detector (40 kt). The main signal for these physics endeavors is the unambiguous appearance of electron neutrinos – which manifest themselves as electron showers – in a beam of muon neutrinos. Their success thus centrally depends upon the accurate reconstruction of showers and specifically of their initial positions, directions, and energies. Both experiments also face the substantial challenge of assembling particles into neutrino interactions, which rarely occur alone in practice. Detectors located close to the surface, such as those of the SBN program, produce images overlaid with cosmic rays, while the future DUNE near detector will observe a high rate of pileup events, with up to twenty neutrino interactions per event.

Electromagnetic (EM) showers exhibit an incoherent branching tree structure in LArTPCs. As an electron propagates through the dense detector medium, it looses energy through ionization and stochastically emits photons until it runs out of energy. Photons then propagate through the noble liquid with a mean free path of 15–30 cm, for energies in the range 10–1000 MeV, before they either produce an electron-positron pair or emit a Compton electron [10]. A single electron or photon creates a cascade of spatially distinct EM particles – referred to as fragments in this study – that may be far removed from one another in the image. Assembling these fragments into coherent shower objects has been a recurrent challenge in LArTPCs that has not yet been fully resolved using traditional programming techniques.

Graph Neural Networks became popular in recent years as a way to leverage the concept of receptive field developed in the context of Convolutional Neural Networks and generalize it to arbitrary objects [11]. The receptive field is no longer exclusively determined by a square neighborhood of pixels in an image but rather defined by an adjacency matrix whose elements indicate

\[
\Delta E = \frac{1}{2} m c^2 \sqrt{1 - \frac{v^2}{c^2}}
\]

\[
E = \frac{1}{2} m c^2 \left(1 - \frac{v^2}{c^2} \right)
\]

\[
E = \frac{1}{2} m c^2 \left(1 - \frac{v^2}{c^2} \right)
\]

\[
E = \frac{1}{2} m c^2 \left(1 - \frac{v^2}{c^2} \right)
\]

\[
E = \frac{1}{2} m c^2 \left(1 - \frac{v^2}{c^2} \right)
\]
whether objects are connected by an edge in a graph. This development is ideally suited to the clustering of EM showers in LArTPCs as they may each be represented by a collection of shower fragments (the graph nodes) that are connected by invisible photons (the graph edges). The task is then to identify the edges that connect fragments within a shower and to tag the fragments that initiate showers, i.e. the primary fragments.

In the case of interaction clustering, distinct sources of activity in the detector can be clustered into separate groups using a GNN by building a graph in which particles are nodes and edges represent correlations between particles. The task in this case is to identify the edges that connect particles that belong to the same interaction.

The study presented in this paper is reproducible using a singularity [12] software container 1, implementations available in the lartpc_mlreco2 repository and a public simulation sample [13] made available by the DeepLearnPhysics collaboration3.

Section II presents the architecture of the reconstruction chain, as applied to the shower clustering task, from the LArTPC image input to the inference stage. Section III outlines the studies that were conducted to optimize the chain. Section IV shows a detailed analysis of the shower reconstruction performance on this sample. Section V describes how the algorithm was adapted to the particle interaction clustering task and provides some performance metrics.

II. RECONSTRUCTION CHAIN

A. Data

The reconstruction chain is schematically illustrated for the shower clustering task in figure 1. The input LArTPC dataset, PILArNet [13], consists of rasterized

---

FIG. 1. Graph Neural Network (GNN) architecture for particle clustering and primary identification. The input set of voxels associated with electromagnetic showers is passed through a density-based clustering algorithm that forms dense shower fragments. Each fragment is encoded into a set of node features in a graph connected by arbitrary edges carrying edge features. Edge and node features are updated through a series of message passing composed of edge and node updaters. The updated edge features are used to constrain the connectivity graph and the updated node features to identify shower primaries.
3D energy deposition images of simulated ionizing particle interactions in liquid argon. An image corresponds to a $\sim 12 \text{ m}^3$ cubic volume of liquid argon with an edge length of 768 voxels ($1 \text{ voxel} = 3^3 \text{ mm}^3$). Each image includes a multiple-particle vertex, i.e., a set of particles originating from a common vertex, overlayed with randomly located track-like cosmic muon trajectories and shower-like instances. An example image is shown in figure 2. This image contains three tracks and two showers originating from the vertex in addition to two muon tracks and a floating shower.

Figure 3 shows the distributions of the number of particles coming from a common vertex in each image, the number of overlayed particles and their respective type compositions. These data emulate a particle density above that expected in an SBN program LArTPC detector. The data is split in two data samples: a training set of 125480 images and a validation set of 22439 images.

![Figure 3](image-url)

**FIG. 3.** Distribution of the number of particles, showers and tracks in each image, originating from a common vertex (blue), randomly scattered (orange) and combined (green).

For the shower clustering task, the set of input voxels is constrained to those associated with electromagnetic (EM) activity. In the scope of this paper, the particle type of each voxel is assumed to be known, as it has been demonstrated that semantic segmentation neural network can identify EM voxels with a 99.4 % voxel-wise accuracy [14].

### B. Fragment clustering

A shower object encompasses all energy deposition associated with a single primary electron or photon and all its subsequent EM daughters. A shower fragment is defined as a spatially dense subset of voxels of a shower instance such that each voxel is in the Moore neighborhood of at least one other voxel in the fragment, i.e., at least ‘touches’ it diagonally. As the ground truth\(^5\) fragments are not known a priori, EM voxels are clustered using the Density Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm [15] with a distance scale set to 1.9. DBSCAN cannot break ground-truth fragments, by definition, as any two touching voxels are merged by this algorithm. It can however merge two or more fragments that belong to separate shower instances into one. Purity is defined as the maximum fraction of voxels in a predicted fragment that belongs to a single instance. In this dataset, fragments reconstructed with DBSCAN contain more than one ground-truth label in 0.2 % of cases, which corresponds to $\sim 2 \%$ of images. Figure 4 shows the purity distribution of the small fraction of fragments that do contain an overlap. It follows a close to uniform distribution between 0.5 and 1.

![Figure 4](image-url)

**FIG. 4.** Distribution of the purity of overlapping shower fragments built using DBSCAN with a distance scale of 1.9. In the top box plot, the blue diamond represents the mean, the orange line the median, the box the IQR and the whiskers span from the 10\(^{th}\) to the 90\(^{th}\) percentiles.

Fragments strictly smaller than 10 voxels are not included in the input to the clustering task as they have no clear directionality. To characterize the impact of this selection on the shower energy resolution, primary showers that are at least 95 % contained in the image volume are selected. The fraction of the total shower energy deposited in fragments of size 10 and above is represented as a function of shower energy in figure 5. The shower completeness is on average $\sim 82.6 \%$, for showers of 100 MeV and above. For lower energy showers, the fraction of energy deposited in small fragments decreases slightly.

\(^4\) A primary electron or photon does not have an EM parent and is neither a delta ray, a Michel electron nor a deexcitation photon.

\(^5\) In the field of computer vision, ground truth refers to the data labels, i.e., a predefined target for the reconstruction.
This selection introduces an average relative uncertainty of 4.2% on the final energy reconstruction.

FIG. 6. Image of the EM shower voxels with a color scale that represents the DBSCAN cluster ID.

The goal of the clustering algorithm is to cluster these shower voxels of an image using the DBSCAN algorithm. The latter is shown on its own in the bottom pad. The green line a is constant fit to the markers above 100 MeV.

Figure 6 shows the fragments constructed upon the shower voxels of an image using the DBSCAN algorithm. The goal of the clustering algorithm is to cluster these fragments together into shower objects.

C. Graph Representation

A graph $G(V,E)$ is a collection of nodes $V$ and edges $E \subseteq V \times V$. Each shower fragment represents a node in a graph. There is an arbitrary number of ways to build a graph between the nodes. The optimal choice of input edges is discussed in section III B. Each node is encoded as a set of $F_v$ features and each edge as a set of $F_e$ features. Multiple ways of extracting these features are studied and optimized in section III B.

D. Message Passing

Message passing is used to communicate information within a graph [11, 16]. At step $s + 1$, edge attributes are updated by combining the features coming from the nodes it connects together with its own through

$$
\epsilon_{ij}^{s+1} = \psi_{\Theta}(x_i^s, x_j^s, \epsilon_{ij}^s),
$$

with $x_i, x_j$ the node feature vectors associated with nodes $i$ and $j$, respectively, $\epsilon_{ij}$ the features of the edge connecting $i$ to $j$ and $\psi$ a differentiable function such as a Multi Layer Perceptron (MLP) [17]. In order to update the node features, the message coming from node $j$ communicated to node $i$ at step $s + 1$ is defined as

$$
m_{ji}^{s+1} = \phi_{\Theta}(x_j^s, \epsilon_{ji}^{s+1}),
$$

with $\phi_{\Theta}$ a differentiable function such as an MLP. The messages coming from the neighborhood $\mathcal{N}(i)$ of node $i$ are then aggregated with its own at each step to update its features following

$$
x_i^{s+1} = \chi_{\Theta}(x_i^s, \square_{\mathcal{N}(i)} m_{ji}^{s+1}),
$$

with $\chi_{\Theta}$ a differentiable function such as an MLP, $\square$ an aggregation function such as sum, mean or max. The specific implementation of the differentiable functions and the number of message passing steps are studied and optimized in section III D.

E. Loss definition

Downstream of the message passing steps, two fully connected linear layers reduce the edge and node features separately to two channels each. The outputs are passed through the softmax function and the second channel is used to create a vector of $N_v$ primary scores for nodes, $s^v$, and a vector of $N_v$ adjacency scores for edges, $s^e$. The binary cross-entropy loss is then applied to node and edge scores alike as follows:

$$
L_v = -\frac{1}{N_v} \sum_i y_i \ln(s_i^v) + (1 - y_i) \ln(1 - s_i^v),
$$

$$
L_e = -\frac{1}{N_e} \sum_{(i,j) \in E} a_{ij} \ln(s_{ij}^e) + (1 - a_{ij}) \ln(1 - s_{ij}^e),
$$

with $y_i$ the primary label of node $i$ and $a_{ij}$ the adjacency label of the edge connecting node $i$ to node $j$. The total loss is defined as $L = L_v + L_e$. The definition of the target adjacency matrix, $A$, is discussed in section III E.
FIG. 7. Schematics of the edge selection mechanism at the inference stage. The partition loss defined in equation 6 is first calculated for an empty graph in which each node forms its own group. Edges are sequentially added in order of decreasing score only if the new partition they form decreases the partition loss. The edge with score 0.6 is not added to the graph because it would put the nodes connected by the edge with score 0.1 in the same group and increase the partition loss.

F. Inference

The network predicts an edge score matrix, \( S^e \), which tries to replicate the predefined ground-truth adjacency matrix, \( A \). In a graph representing a connectivity map, \( A \) is always such that, if \( a_{ij} = 1 \), then nodes \( i \) and \( j \) belong to the same group. The reverse statement does not have to hold, as nodes \( i \) and \( j \) may not be connected directly but still be linked through an indirect path.

Figure 7 schematically illustrates how the score matrix is converted into a node partition prediction. At the inference stage, one has to find the optimal node partition, \( \hat{\mathbf{g}} \), such that, if \( s_{ij}^e \) is close to 1, nodes \( i \) and \( j \) are encouraged to be put in the same true group. Mathematically, this corresponds to minimizing the partition cross-entropy loss defined as

\[
L(S^e|\mathbf{g}) = -\frac{1}{N_e} \sum_{(i,j) \in E} \delta_{g_{ij}} \ln(s_{ij}^e) \\
+ (1 - \delta_{g_{ij}}) \ln(1 - s_{ij}^e),
\]

for \( \mathbf{g} \), i.e. \( \hat{\mathbf{g}} = \min_{\mathbf{g}} L(S^e|\mathbf{g}) \), with \( \delta \) the Kronecker delta. If an edge is not in the input graph, it does not contribute to the grouping optimization loss.

The cardinality of the set of all possible partitions of a set of \( n \) nodes, \( G \), corresponds to the Bell number \( B_n \). This number grows quickly with the number of nodes to prohibitively large values that rule out brute-force optimization. Instead, edges are considered sequentially to be added to a predicted adjacency matrix, \( \hat{A} \), in order of decreasing edge score. At each step, the partition score is evaluated by running the Union-Find algorithm [18] on the predicted matrix. The edge is permanently added to \( \hat{A} \) if the new partition improves the loss defined in equation 6. The optimizer stops when the next available edge has a score below 0.5.

Given the predicted partition of the graph nodes, \( \hat{\mathbf{g}} \), the primary nodes are identified by the picking those with the highest primary score in each group.

III. OPTIMIZATION

A. Training regiment

In this section, the reconstruction steps are optimized to maximize the clustering accuracy in a model that uses ground-truth shower fragments as an input and does not attempt to predict shower primaries. Variations are studied with respect to a baseline model in which

- the input node and edge features are geometric;
- the input graph is a complete graph;
- the number of message passings is 3;
- the ground-truth adjacency matrix corresponds to a cluster graph built upon groups;
- the batch size is 128;
- the Adam optimizer [19] is used with a learning rate is 0.0025.

The reconstruction chain is trained for 25 epochs of the training set for each configuration under study. The edge classification accuracy and cross-entropy loss are cross-validated with 10000 events from the validation set every \( \sim 1 \) epoch to check for overtraining.

B. Feature extraction

Each shower fragment has to be encoded into a set of node features and each edge in the input graph can be provided with a set of features of its own. Two methods of feature extraction have been considered in the context of this paper and are presented and compared in this subsection: Geometric and CNN.

Geometric features are a list of summary statistics of the distribution of fragment voxels in Euclidean space. It includes the following 22 features:

- normalized covariance matrix (9 features);
- normalized principal axis (3 features);
In this study, the initial point of a fragment is acquired by picking the center of the voxel, $v_s$, closest to the true simulated particle first energy deposition. In a realistic setting, it will be reconstructed using the Point Proposal Network [20]. The initial direction, $\hat{d}$, is estimated by calculating the normalized mean direction from the initial point, $v_s$, to all the other fragment voxels within a neighborhood distance $R_n$ of the initial point, i.e.

$$\hat{d} = \langle v \rangle / |\langle v \rangle| = \frac{1}{N_s} \sum_{\{i | d_{si} \leq R_n\}} (v_i - v_s),$$  (7)

with $d_{si}$ the Euclidean distance between $v_i$ and $v_s$ and $N_s$ the number of voxels in the neighborhood. The radius was optimized to $R_n = 5$ by minimizing the spread of the angle between this direction estimate and the true normalized particle momentum, $d = p/|p|$, as shown for multiple radial cut values in figure 8. In the following, the importance of the initial point and direction for the clustering task is studied by training the model without them (referred to as NI later).

The geometric edge features include 19 components:

- closest points of approach (CPAs) (6 features);
- displacement between CPAs (3 features);
- outer product of displacement (9 features);
- length of displacement (1 feature).

The CNN feature extractor treats each fragments as an individual node image and each pair of fragment as an edge image. The images are passed through a sparse Convolutional Neural Network (CNN) which consists of alternating ResNet blocks [21] and strided convolutions which progressively reduce the spatial size of each image while increasing the number of features in each channel. In this study, the kernel size is set to 5, the number of strided convolutions to 8 and the input number of filters to 32. The features of the most spatially compressed $3^3$ voxels image are average pooled to form a vector of 64 features per node and 64 features per edge.

Figure 9 shows the training and validation curves for each type of feature extractor, produced using the training and validation datasets, respectively. Removing the initial point and initial direction (NI) from the fragments reduces the edge prediction accuracy by $\sim 1\%$. The CNN features are tested individually or in combination with the geometric features. The CNN as a standalone encoder quickly and dramatically overfits the training set. The addition of the CNN features to the baseline geometric features does not measurably improve the global edge classification loss.

FIG. 8. Boxplot of the angle between the reconstructed direction of a shower fragment, $d$, and the normalized true particle momentum, $d = p/|p|$, as shown for multiple radial cut values in figure 8. In the following, the importance of the initial point and direction for the clustering task is studied by training the model without them (referred to as NI later).

FIG. 9. Edge score loss and edge prediction accuracy for the different encoders under considerations. The training curves are represented as lines and the validation points as round markers with statistical error bars.

C. Input graph

The input set of fragments is partitioned into groups based on an adjacency score matrix. An edge is given a score only if it appears in the input graph. Several graph construction methods were studied to find the optimal receptive field for nodes:

- complete graph (all possible pairwise edges);
- Delaunay graph (edges in the spatial Delaunay triangulation of the input voxels only);
- MST graph (edges in the spatial minimum spanning tree of the input voxels only);
• 5NN graph (edges connecting each node with its 5 nearest neighbors only).

These graphs are all defined undirected, so that if a message path exists from node $i$ to node $j$, its reciprocal path exists as well. If either direction of a path is activated by the network, it connects two nodes together.

Restricting the number of edges in the input graph can potentially simplify the clustering task by allowing for the nodes to only focus on messages coming from nodes that are adjacent in the input graph. To be suitable, an input graph must include at least one essential path from each node to at least one other node that belongs to the same group, without passing through a node that does not. Figure 10 shows the fraction of essential edges that appear in the input graph, i.e. the fraction of nodes that are reachable through an essential path. It shows that the MST graph is the most inefficient proposed network, on average missing a prohibitively large $\sim 2.3\%$ of the edges necessary to make correct predictions. All the other graphs are viable options, although their accuracy will be limited in images missing essential edges.

Figure 11 shows the training and validation curves for the aforementioned input graph structures. Figure 12 shows the adjusted Rand index clustering metric [22] on the test set for each configuration. The complete graph, which is the one that includes all possible message passing routes, performs best. Delaunay graphs perform similarly – at a much greater computational cost – while other two maintain that number. In this study, regardless of the step number, $F^s_v + F^s_e$ is set to 64. The edge updater MLP consists of three linear layers, each preceded by a 1D batch normalization layer and followed by a LeakyRELU layer of leakiness 0.1. The first linear layer brings the number of features to 64, the other two maintain that number.

The nodes are updated from $F^s_v$ features to $F^{s+1}_v$ features by a function of neighboring nodes and the edge attributes that connect them, as summarized by equations 2 and 3. Five Pytorch Geometric [23] layers

![FIG. 11. Edge score loss and edge prediction accuracy for the different input graphs under consideration. The training curves are represented as lines and the validation points as round markers with statistical error bars.](image)

![FIG. 12. Adjusted Rand index (ARI) distributions on the test dataset for the four input graphs under consideration. In the top box plot, the blue diamonds represent the means, the orange lines the medians, the boxes the IQRs and the whiskers span from the 10th to the 90th percentiles.](image)

D. Message passing

At a message passing step $s + 1$, the edge features are updated by an edge updater which maps $2F^s_v + F^s_e$ features coming from the nodes it connects and its own features to $F^{s+1}_e$ features, with $F^s_v$ the number of node features at step $s$ and $F^s_e$ the number of edge features at step $s$. In this study, regardless of the step number, $F^{s+1}_e$ is set to 64. The edge updater MLP consists of three linear layers, each preceded by a 1D batch normalization layer and followed by a LeakyRELU layer of leakiness 0.1. The first linear layer brings the number of features to 64, the other two maintain that number.
were studied in the context of this paper: MetaLayer, NNConv, EdgeConv, GATConv and AGNNConv.

The MetaLayer [16] uses two successive MLPs to combine the edge features, the node features and their neighbor features. The first MLP combines the $F^s_v$ source node features together with the $F^{s+1}_v$ edge features using three linear layers, each preceded by a 1D batch normalization and followed by a LeakyReLU layer of leakiness 0.1. This produces one message per edge $e_{ij}$, $m^{s+1}_{ij}$, each containing $F^{s+1}_v$ features. The second MLP combines the $F^s_v$ target node features with the averaged $F^{s+1}_v$ message features using the same architecture as the first MLP. At each message passing step, $F^{s+1}_v$ is set to 64.

The NNConv [24] layer is defined as

$$x^{s+1}_i = \Theta x^s_i + \sum_{j \in \mathcal{N}(i)} x^s_j \cdot h_{\Theta}(e_{j,i}^{s+1}),$$

with $\Theta$ an $F^{s+1}_v \times F^s_v$ matrix of weights and $h_{\Theta}$ an MLP that maps $F^{s+1}_v$ edge features to an $F^{s+1}_v \times F^s_v$ matrix. In this study, the MLP is composed of three layers of a batch normalization, a linear layer and a LeakyReLU function of leakiness 0.1. The first layer increases the number of features from $F_v$ to $F^{s+1}_v \times F^s_v$ and the following two keep it constant.

The EdgeConv [25] layer is defined as

$$x^{s+1}_i = \sum_{j \in \mathcal{N}(i)} h_{\Theta}(x^s_i || x^s_j - x^s_i),$$

with $||$ the concatenation operator and $h_{\Theta}$ an MLP that maps $2F^s_v$ concatenated features to $F^{s+1}_v$ features. The implementation of the MLP uses an identical implementation to that of the NNConv layer.

The GATConv [26] layer uses the concept of attention:

$$x^{s+1}_i = \alpha x^s_i + \sum_{j \in \mathcal{N}(i)} \alpha_{ij} x^s_j,$$

$$\alpha_{ij} = \frac{\exp \left( LR(a^T \Theta x^s_j || \Theta x^s_i) \right)}{\sum_{j \in \mathcal{N}(i) \cup \{i\}} \exp \left( LR(a^T \Theta x^s_j || \Theta x^s_i) \right)},$$

with $LR = \text{LeakyReLU}$ and $a$ the attention weight vector of size $2F^s_v$. The weight of the message coming from each node in the neighborhood of $i$ is explicitly learned as a function of the node features.

The AGNNConv [27] node updater uses a slightly different attention mechanism:

$$X^{s+1} = P^s X^s,$$

$$P^s_{ij} = \frac{\exp (\beta \cos(x^s_i, x^s_j))}{\sum_{j \in \mathcal{N}(i) \cup \{i\}} \exp (\beta \cos(x^s_i, x^s_j))},$$

with $\beta$ a learnable parameter. Note that for both of the attention-based layers, that node features do not take into account the edge features.

Figure 13 shows the training and validation curves for the functions under study and for three iterations of message passing. The MetaLayer node updater performs best, NNConv is comparable but overtrains faster at a large number of epochs. Note that, for this task, the added complexity through the use of an MLP is evidently useful. All layers that explicitly include the edge features – or the difference between node features as a substitute in the EdgeConv function – perform similarly. Figure 14 shows the training and validation curves using the MetaLayer node updater with a number of message passing varying between 1 and 5. Adding more than three message passing steps does not measurably improve the edge classification accuracy.

FIG. 13. Edge score loss and edge prediction accuracy for the different node updater architecture. The training curves are represented as lines and the validation points as round markers with statistical error bars.

FIG. 14. Edge score loss and edge prediction accuracy for the different number of message passing steps. The training curves are represented as lines and the validation points as round markers with statistical error bars.

E. Ground-truth

The ground-truth adjacency matrix may be defined in different ways. The only requirement is that it forms
at least a tree within each group of nodes, so that the true partition can be predicted on an edge basis. One possibility is to set the value of edges that connect two nodes within the same group to 1 and all others to 0. This encourages the network to build a cluster graph, i.e a disjoint union of complete graphs.

The second possibility uses the score predictions to define a ground-truth. A tree of $n - 1$ edges is built on each true group of $n$ nodes so as to maximize the sum of adjacency scores of the tree edges. The CE loss is then only applied to those edges in the trees and those separating different node groups. This allows the network freedom as to which edge to turn on, as long as it builds a forest, i.e. a disjoint union of trees. In the following discussion, the first ground-truth is referred to as the cluster target and the second as the forest target.

Figure 11 shows the training edge accuracy and edge loss for the two ground-truths defined above. Figure 12 shows their adjusted Rand index (ARI) [22] distribution on the test set. Both targets yield very similar results with a small lead for the baseline cluster target.

FIG. 15. Edge score loss and edge prediction accuracy for the different ground-truths under consideration. The training curves are represented as lines and the validation points as round markers with statistical error bars.

FIG. 16. Adjusted Rand Index (ARI) distributions for the different ground-truths under consideration. In the top box plot, the blue diamonds represent the means, the orange lines the medians and the whiskers span from the 10th to the 90th percentiles.

FIG. 17. Loss and classification accuracy of nodes and edges for the full shower reconstruction model, with and without initial points. The training curves are represented as lines and the validation points as round markers with statistical error bars.

IV. RESULTS

A. Training

The baseline model is trained for 25 epochs on the edge and node prediction tasks using the DBSCAN-formed shower fragments and achieves a loss and accuracy summarized in figure 17. The edge classification accuracy is not affected by the addition of the node classification task nor the use of DBSCAN. The primary classification accuracy is close to 1 when initial points are known.

B. Shower grouping

Figure 30 shows example outputs of the shower reconstruction algorithm for the four events that contain the most fragments in the test set. All four events have a high clustering accuracy, only missing or merging small fragments incorrectly. The top event highlights the importance of the partition loss optimization at the inference stage. Some edges are connecting two separate showers together but the loss minimization allows for the recovery of an almost perfect partition. The bottom left group of the fourth event originates from the same shower but the primary is out of volume. The network correctly associated them together but would not be penalized for making a mistake there. Also note that there is no primary identification mistake in these examples.
Three clustering metrics are used to systematically characterize the performance of the shower clustering algorithm: efficiency, purity and adjusted Rand index (ARI). The efficiency and purity are defined as:

\[
\text{Efficiency} = \frac{1}{N} \sum_{i=1}^{N_t} \max_j |c_j \cap t_i|, \tag{12}
\]

\[
\text{Purity} = \frac{1}{N} \sum_{i=1}^{N_p} \max_j |c_i \cap t_j|, \tag{13}
\]

with \(N_t\) the true number of showers, \(N_p\) the predicted number of showers, \(N\) the total number of voxels in the image, \(t_k\) the \(k\)th true cluster and \(c_k\) the \(k\)th predicted cluster. The Rand index (RI) is defined as the accuracy on binary edge classification between any two pair of voxels; the ARI adjusts for random chance by shifting this measure with respect to the average RI obtained for all possible permutations of the predicted labels, i.e.

\[
\text{ARI} = \frac{\text{RI} - E(\text{RI})}{\max(\text{RI}) - E(\text{RI})}, \tag{14}
\]

with \(E\) the expectation value. Note that if one of the partitions contains a single cluster, a single voxel mistake yields an ARI of 0, as permutations do not affect RI.

Figure 18 shows the clustering metrics associated with the baseline model applied to the test set. The cases with ARI = 0 represent \(\sim 1\%\) of all events in this test set and are omitted from the ARI distribution. Figure 19 shows the number of reconstructed showers as a function of the number of true showers in a single image. To prevent small fragments that are either omitted or merged to affect the histogram content, only shower instances with more than 100 voxels (\(\sim 60\) MeV) are included. In 95.03\% of events, the estimated shower count is exact.

**C. Primary identification**

Figure 20 shows the distributions of primary scores for ground-truth primary and secondary nodes in the test set. This study shows that 0.08\% of secondary fragments have a score larger than 0.5 and 0.84\% of primary fragments have a score below 0.5.

Given the partition predicted by the network, a single primary fragment is assigned to each shower group by selecting the one with highest score. This scheme yields a group-wise primary identification accuracy of 99.77\% for showers consisting of two or more fragments. This task is relatively trivial given an understanding of the direction of travel of the shower. The prior knowledge of fragment initial points helps, but even without them, the primary identification accuracy is still at 98.94\%.
D. Shower energy resolution

For each ground-truth shower instance in the dataset, the total amount of energy that it deposits inside the image volume is integrated – including the fragments smaller than size 10 that are not in the input to the reconstruction chain – to form the ground-truth shower energy, $E$. For each true shower, the reconstructed cluster with the highest overlap is selected and the energy of its voxels is summed to form an energy estimate, $\hat{E}$. This estimate is multiplied by a fudge factor of 1.211 to compensate for the energy lost in small fragments measured in figure 5. In order to assess the importance of the calorimetric information on the shower energy resolution, the energy is also estimated using the voxel count alone divided by a factor 1.69, obtained by fitting the relation $N = (1.69 \pm 0.06)E$ to the shower energy residuals for the showers that are at least 95% contained inside the images of test dataset. The residuals show that the uncertainty on the shower energy is mostly driven by the prior fragment size selection. Figure 23 shows the $1\sigma$ energy resolution as a function of the shower energy. The uncertainty decreases as the shower energy increases and reaches an accuracy around 5% at 1 GeV.

FIG. 21. Number of shower voxels contained in shower fragments of size 10 and above as a function of the total energy deposited by the shower.

Figure 22 shows a distribution of the relative shower energy residuals for the showers that are at least 95% contained inside the images of test dataset. The residuals are provided with and without leveraging the calorimetric information. These results show that the uncertainty on the shower energy is mostly driven by the prior fragment size selection. Figure 23 shows the $1\sigma$ energy resolution as a function of the shower energy. The uncertainty decreases as the shower energy increases and reaches an accuracy around 5% at 1 GeV.

E. Shower angular resolution

For each ground-truth shower in the dataset, its direction is measured by normalizing its primary momentum vector to its norm, $d = \frac{p}{|p|}$. For each true shower, the direction is estimated by taking the mean direction from the predicted primary initial point to the primary points with a neighborhood radius $R_n$, $d$, as shown in equations 7. Setting $R_n$ to a constant is suboptimal because the geometry of primary fragments can vary significantly from one shower to another. Smaller radii are preferable for fragments that curve or branch out a lot, but larger radii are advantageous for mostly linear showers.

The radius is optimized in order to minimize the relative deviation of the points from a straight line. The primary fragment points are ordered from closest to farthest from the initial point, $\{x\}^n_{k=1}$. The mean, $\bar{v}_k$, and covariance matrix, $\Sigma_k$, are first evaluated for the closest three points (as the covariance matrix is undefined for $k < 3$). The mean and matrix are then iteratively updated for $k = 4, \ldots, n$ following

$$\bar{v}_k = \frac{1}{k} ((k-1)\bar{v}_{k-1} + v_k),$$

FIG. 22. Reconstructed relative shower energy residual distribution as a function of the shower energy. In the top box plot, the blue diamonds represent the means, orange lines the medians, the boxes the IQRs and the the whiskers span from the $10^{th}$ to the $90^{th}$ percentiles. ‘True’ uses the true energy of true clusters, ‘Calorimetry’ the energy depositions of reconstructed clusters and ‘Count’ a constant factor applied to the reconstructed voxel count.

FIG. 23. Reconstructed relative shower energy residual distribution as a function of the shower energy. The orange markers on the top pad represent the means and their error bars the RMS; the latter is shown on its own in the bottom pad.
\[
\Sigma_k = \frac{k-1}{k} \Sigma_{k-1} + \frac{1}{k-1} (v_k - \bar{v}_k)(v_k - \bar{v}_k)^T.
\] (16)

For each combination of points, \(k\), the ordered eigenvalues of the covariance matrix, \(\{\lambda_{k,i}\}_{i=1}^{3}\), are evaluated. The optimal neighborhood of points minimizes the spread around the principal axis, i.e.

\[
k^* = \min_k \frac{\lambda_{k,1} + \lambda_{k,2}}{\lambda_{k,3}}.
\] (17)

Figure 24 shows the angular distribution between the true direction and the estimate, \(\theta = \arccos(\hat{d} \cdot d)\), for all the true showers in the dataset. The residual angle distribution has a mode of \(\sim 2^\circ\), a mean of 6.1° and a median of 3.8°, when using the optimized neighborhood, \(R^*\). The distributions for fixed neighborhood radii perform significantly worse. A radius of 5, while on average optimal for all fragments as shown in figure 8, carries a large uncertainty when used for primary fragments. Figure 25 shows the angular resolution as a function of the shower energy. It shows that the resolution improves significantly with energy to reach a mean as low as \(\sim 2.0^\circ\).

![Figure 25. Reconstructed shower direction residual distribution as a function of the shower energy.](image)

**FIG. 25.** Reconstructed shower direction residual distribution as a function of the shower energy. The orange markers on the top pad represent the mean and their error bars the RMS; the former is shown on its own in the bottom pad.

set. Events with an efficiency < 0.9 represent \(\sim 0.7\%\) of this dataset. This event showcases the difficulty to choose whether to merge large colinear fragments or to separate them. The third row shows a the event with the lowest ARI and the fourth with an ARI of 0. The last example highlights that a clustering may have an ARI of 0 but be mostly accurate, if the number of true or predicted showers is one.

There is a total of 119 showers in the whole test set that have a misidentified primary. The majority of those mistakes stem from an incorrect partition of the nodes. The remaining mistakes can be attributed to ambiguous shower starts that do not have a fragment clearly upstream of the others. An example is provided in figure 26. The network picks the leftmost fragment but the one directly to its right is the labeled shower start. The network shows its uncertainty by giving scores of 0.76 and 0.13 to the left and right fragments, respectively.

![V. INTERACTION CLUSTERING](image)

**V. INTERACTION CLUSTERING**

A. Modifications

Interaction clustering is defined as the association of particle instances together into groups that share a common particle ancestor. In this study, the individual particle instances are assumed to be known a priori from the previous reconstruction steps. In the full reconstruction chain, the shower instances will be provided by the reconstruction algorithm described in the previous sections while tracks, Michel and Deltas are to be clustered by a separate algorithm such as DBSCAN [15] or a CNN-based dense clustering algorithm [28].

Images simulated for this dataset only contain a single interaction vertex and multiple stray tracks and showers.

F. Mistakes analysis

A study of the events with low clustering purity reveals that the algorithm occasionally merges showers when the direction vector of one of its fragments can clearly be back-propagated to another shower fragment from a distinct instance. This may stem from an inconsistency between the true photon momentum and the local direction estimate of the fragment. The top row of figure 31 shows an event with a purity of 0.51 in the test set. Events with a purity < 0.9 represent \(\sim 1\%\) of this dataset. The middle row shows an event with an efficiency of 0.54 in test...
FIG. 26. Primary scores for an ambiguous shower start with a color scale that ranges from 0 (black) to bright yellow (1).

In order to teach the network to separate multiple interaction vertices, several images may be stacked together. At the training stage, the number of images that are stacked together before being fed to the network follows a Poisson distribution of mean 2. Figure 27 shows an example of two stacked images and their particle labels.

FIG. 27. Particle labels of a superimposition of two events in the test set.

This task utilizes an identical reconstruction chain to that used for the shower clustering. The input to the chain consists of particle instances instead of shower fragments and the target is interaction instances. The edge features are identically defined while node features are extended by adding the number-encoded particle class (0–4 corresponding to shower, track, Michel and delta rays, respectively), the mean and RMS energy deposition and the terminal point of tracks (other classes do not have well defined end points and are given a duplicate of the initial point instead).

Downstream the message passing stage, the updated node features are not explicitly used to make any prediction. The edge features are the basis for an adjacency matrix prediction, while the groups are extracted by using the method described in section II F. Figure 28 shows the training and validation edge classification loss and accuracy for the interaction clustering task. These metrics are evaluated with and without the end point information; adding the endpoints to the particle instances increases the edge classification accuracy by $\sim 0.2\%$.

FIG. 28. Edge score loss and edge prediction accuracy for the different interaction clustering models. The training curves are represented as lines and the validation points as round markers with an error bar.

B. Performance

Figure 32 shows the output of the interaction clustering algorithm for four randomly selected events in the test set, with one to four interaction vertices stacked together. All four events have a high clustering accuracy, only missing or merging small particles incorrectly.

The metrics described in section IV B are used to systematically characterize the performance of the reconstruction chain applied to the interaction clustering task. Figure 29 shows the clustering performance as a function of the number of images that are superimposed. As shown in figure 3, each image contains one neutrino-like interaction of $4.3 \pm 1.6$ particles overlayed with $3.8 \pm 1.7$ randomly scattered cosmic-like interactions. For an image of $\sim 12\text{m}^3$, this corresponds to an interaction density of $0.40 \pm 0.14\text{interactions/m}^3$, which increases linearly with the number of superimposed images. The density observed of a single image, for instance, is equiva-
lent to $\sim 120$ interactions in a single ICARUS image, far above the expected rate \cite{5}. A stack of two images contains two neutrino-like interactions, which corresponds to $\sim 18$ such interactions in the DUNE-ND volume, close to the maximum expected rate \cite{9}, overlayed with $\sim 30$ cosmic rays, which is unrealistically large. This demonstrates that this algorithm should easily deal with the expected rate of interactions in the foreseeable future.

![Figure 29](image)

**FIG. 29.** Interaction clustering metrics as a function of the number of interactions in the image. The diamonds represent the means, the lines the medians, the boxes the IQRs and the whiskers span from the 10\textsuperscript{th} to the 90\textsuperscript{th} percentiles.

### C. Mistakes analysis

Figure 33 shows the three events that are reconstructed with the lowest purity, efficiency and ARI on the first three rows, respectively, and an event with an ARI of 0. The first event exhibits a purity of 56.1\% due to a cosmic muon crossing and overlapping one of the vertex tracks. Events with purity $< 0.9$ represent $\sim 0.6\%$ of this test set. The second event has an efficiency of 49.7\% as the correlation between showers is not found sufficient by the network to associate them in an interaction. This may be due to a direction estimate not accurately representing the shower momentum or the vertex not being clearly defined by a track. Events with efficiency $< 0.9$ represent $\sim 0.8\%$ of this test set. The bottom two rows show an event with an ARI of -1.3\% and one with an ARI of 0. These two examples have a very low ARI but only contain minor mistakes, merging a small fragment it should not while omitting another.

### VI. CONCLUSION

Graph Neural Networks (GNNs) are an ideally suited method to tackle the clustering of spatially detached objects in Liquid Argon Time Projection Chambers (LArTPCs). A GNN-based reconstruction chain was developed to cluster electromagnetic showers and particle interactions. This paper studied its performance on a generic 3D sample of particle interactions in liquid argon and demonstrated a clustering efficiency and purity well above 99\% for both tasks. A good shower energy resolution is a core requirement for the upcoming SBN program and DUNE experiment to reach their scientific goals. The reconstruction of the shower direction will be of central importance when matching neutral pion decay showers together or when back-propagating photons to a vertex. The clustering of particle into interactions will become essential for future high-rate LArTPCs and the GNN algorithm developed here shows that this can be achieved. The algorithm described in this paper will be part of an end-to-end, machine-learning-based reconstruction chain developed at SLAC for all LArTPCs.
