Flows of X-ray gas reveal the disruption of a star by a massive black hole

Peter Maksym¹¹, Richard Mushotzky⁵, Paul O’Brien¹³, Frits Paerels¹⁴, Jelle de Plaa², Enrico Ramirez-Ruiz¹⁵, Tod Strohmayer⁷ & Nial Tanvir¹³

Tidal forces close to massive black holes can violently disrupt stars that make a close approach. These extreme events are discovered via bright X-ray⁴-⁷ and optical/ultraviolet⁴-⁶ flares in galactic centres. Prior studies based on modelling decaying flux trends have been able to estimate broad properties, such as the mass accretion rate⁴-⁶. Here we report the detection of flows of hot, ionized gas in high-resolution X-ray spectra of a nearby tidal disruption event, ASASSN-14li in the galaxy PGC 043234. Variability within the absorption-dominated spectra indicates that the gas is relatively close to the black hole. Narrow linewidths indicate that the gas does not stretch over a large range of radii, giving a low volume filling factor. Modest outflow speeds of a few hundred kilometres per second are observed; these are below the escape speed from the radius set by variability. The gas flow is consistent with a rotating wind from the inner, super-Eddington region of a nascent accretion disk, or with a filament of disrupted stellar gas near to the apocentre of an elliptical orbit. Flows of this sort are predicted by fundamental analytical theory⁰ and more recent numerical simulations⁹-¹⁴.

ASASSN-14li was discovered in images obtained on 22 November 2014 (modified Julian day MJD 56,983), at a visual magnitude of $V = 16.5$ (ref. 15) by the All-Sky Automated Survey for Supernovae (ASASSN). Follow-up observations found this transient source to coincide with the centre of the galaxy PGC 043234 (originally Zwicky VIII 211), to within 0.04 arcseconds (ref. 15). This galaxy lies at a redshift of $z = 0.0206$, or a luminosity distance of 90.3 Mpc (for $H_0 = 73$ km s⁻¹ Mpc⁻¹, $Ω_{\text{matter}} = 0.27$, $Ω_Λ = 0.73$), making ASASSN-14li the closest disruption event discovered in over ten years. The discovery magnitudes indicated a substantial flux increase over prior, archival optical images of this galaxy. Follow-up observations with the Swift space observatory’s X-ray Telescope⁶,¹⁷ (XRT) established a new X-ray source at this location¹⁵.

Archival X-ray studies rule out the possibility that PGC043234 harbours a standard active galactic nucleus that could produce bright flaring. PGC043234 is not detected in the ROSAT All-Sky Survey¹⁸. Using the online interface to the data, the background count rate for sources detected in the vicinity is 0.002 counts s⁻¹ arcmin⁻². With standard assumptions (see Methods), this rate corresponds to a luminosity of $L = 4.8 \times 10^{40}$ erg s⁻¹, which is orders of magnitude below a standard active nucleus.

Theory predicts that early tidal disruption event (TDE) evolution should be dominated by a bright, super-Eddington accretion phase, and be followed by a characteristic $t^{-5/3}$ decline as disrupted material interacts and accretes⁸,¹⁹. Detections of winds integral to super-Eddington accretion have not been reported previously, but $t^{-5/3}$ flux decay trends in the ultraviolet part of the spectrum (where disk emission from active nuclei typically peaks) are now a standard signature of TDEs in the literature⁶-⁷. Figure 1 shows the flux decay of ASASSN-14li, as observed by Swift. A fit to the UVM2-filter data assuming an index of $α = -5/3$ gives a disruption date of $t_0 = 56,948 \pm 3$ (MJD). The V-band light is consistent with a shallower $t^{-5/12}$ decay; this can indicate direct thermal emission from the disk, or reprocessed emission⁴,¹⁴ (see Methods).

We triggered approved XMM-Newton programs to study ASASSN-14li soon after its discovery. Although the space observatory XMM-Newton carries several instruments, the spectra from the two Reflection Grating Spectrometer (RGS) units are the focus of this analysis. We were also granted a Director’s Discretionary Time

Each spectrum was fitted with a simple blackbody continuum, modified by photoionization absorption via the pion model, and interstellar absorption in the host galaxy PGC 043234 and the Milky Way. The fits were made using SPEX, minimizing a $\chi^2$ statistic. In all cases, 1σ errors are quoted. Where a parameter is quoted with an asterisk, the listed parameter was not varied. X-ray fluxes $F_{kx}$ and luminosities $L_{kx}$ listed with the subscript 'b' for 'broad' were extrapolated from the fitting band to the 1.24–124 Å band; those with the subscript 'f' represent values for the 18–35 Å fitting band. Interstellar column densities $N_{H}$ are separately measured for the Milky Way ($N_{HMW}$) at zero redshift and the host galaxy PGC 043234 ($N_{HIG}$) at a redshift of $z = 0.0206$. These parameters were measured in the XMM-Newton ‘long stare’ and then fixed in fits to other spectra. Variable parameters in the photoionization model are listed together; the negative $v_{esc}$ values indicate a blueshift relative to the host galaxy. $\chi^2$ is the ionization parameter of the gas, $v_{rms}$ is the root-mean-square velocity width of the spectral lines, $k$ is Boltzmann’s constant, $T$ is temperature and $\nu$ is the number of degrees of freedom.

observation with the Chandra X-ray Observatory, using its Low Energy Transmission Grating spectrometer (LETG), paired with its High Resolution Camera for spectroscopy (HRC-S).

The 18–35 Å X-ray spectra of ASASSN-14li are clearly thermal in origin, so we modelled the continuum with a single blackbody, modified by interstellar absorption in PGC 043234 and the Milky Way, and absorption from blueshifted, ionized gas local to the TDE. The self-consistent photoionization code pion$^{10}$ was used to model the complex absorption spectra (see Table 1 and Methods).

Assuming that the highest bolometric luminosity derived from fits to the high-resolution spectra ($L = 3.2 ± 0.1 \times 10^{49}$ erg s^{-1}) corresponds to the Eddington limit, a black-hole mass of $2.5 \times 10^{6} M_{\odot}$,

Figure 2 | The high-resolution X-ray spectra of ASASSN-14li reveal blueshifted absorption lines. Spectra from the ‘long stare’ with XMM-Newton and the combined Chandra spectrum are shown. XMM-Newton spectra from the RGS1 and RGS2 units are shown in black and blue, respectively; the RGS2 unit is missing a detector in the 20–24 Å band. The best-fit photoionized absorption model for the outflowing gas detected in each spectrum is shown in red (see Methods), and selected strong lines are indicated. Below each spectrum, the goodness-of-fit statistic ($\chi^2/\nu$) is shown before (cyan) and after (black) modelling the absorbing gas. The errors on the spectra are 1σ confidence limits on the flux in each bin.

Figure 3 | The temperature of the blackbody continuum emission from ASASSN-14li is steady over time. The temperature measured in simple blackbody fits to Swift/XRT monitoring observations is plotted versus time. Errors are 1σ confidence intervals. The temperature is remarkably steady, contrasting strongly with the declining fluxes shown in Fig. 1. Recent theory suggests that winds may serve to maintain steady temperatures in some TDEs14.

Figure 2 shows the best-fit model for the spectra obtained in the 'long stare' with the XMM-Newton/RGS (see Table 1 and Methods). An F-test finds that photoionized X-ray absorption is required in fits to these spectra at more than the 27σ level of confidence, relative to a spectral model with no such absorption. The model captures the majority of the strong absorption lines, giving χ² = 870.5 for 563 degrees of freedom (see Table 1). The strongest lines in the spectrum coincide with ionized charge states of N, O, S, Ar and Ca. Only solar abundances are required to describe the spectra. The Chandra spectrum independently confirms these results in broad terms, and requires absorption at more than the 6σ level of confidence.

A hard lower limit on the radius of the absorbing gas is set by the blackbody continuum. The best radius estimate probably comes from variability timescales within the XMM-Newton 'long stare'. Analysis of specific time segments within the 'long stare', as well as flux-selected segments, reveals that the absorption varies (see Table 1 and Methods). This sets a relevant limit of r ≤ 3 × 10¹⁵ cm, where r is the radius of the absorbing gas relative to the central engine, c is the speed of light, and δt is the time interval of the variability. Although the column density and ionization do not vary significantly, the blueshift of the gas does. During the initial third of the observation, the blueshift is larger, but falls to vshift ≈ −130 ± 70 km s⁻¹ in the final two-thirds. Shorter monitoring observations with XMM-Newton reveal evolution of the absorbing gas, including changes in ionization and column density, before and after the 'long stare' (see Table 1 and Methods).

Fundamental theoretical treatments of TDEs predict an initial near-Eddington or super-Eddington phase6; this is confirmed in more recent theoretical studies9,12,21. The high-resolution X-ray spectra were obtained within the predicted time frame for super-Eddington accretion, for our estimates of the black-hole mass22. Although the ionization parameter of the observed gas is high, the ionizing photon distribution peaks at a low energy, and the wind could be driven by radiation force. Such flows are naturally clumpy, and may be similar to the photospheres of novae23. Given the strong evidence of an accretion disk in our observations of ASASSN-14li, the X-ray outflow is best associated with a wind from the inner regions of a nascent, super-Eddington accretion disk. The local escape speed at an absorption radius of r ≈ 10⁸ GM/c² (appropriate for M ≈ 10⁶M☉, G is Newton's gravitational constant) exceeds the observed outflow line-of-sight speed of the gas, but Keplerian rotation is not encoded in absorption, and projection effects are also important. The small width of the absorption lines relative to the escape velocity may also indicate a low volume filling factor, consistent with a clumpy outflow or shell.

The existing observations show a general trend towards higher outflow speeds with time. Corresponding changes in ionization and column density are more modest, and not clearly linked to outflow speed24. However, some recent work has predicted higher outflow speeds in an initial super-Eddington disk regime, and lower outflow speeds in a subsequent thin disk regime8,12. An observation in an earlier, more highly super-Eddington phase might have observed broader lines and higher outflow speeds; future observations of new TDEs can test this.

Figure 3 shows the time evolution of the blackbody temperature measured in Swift/XRT monitoring observations. The temperature is remarkably constant, especially in contrast to the optical/ultraviolet decline shown in Fig. 1. Observations of steady blackbody temperatures, despite decaying multi-wavelength light curves in some TDEs25,26, have recently been explained through winds14. Evidence of winds in our data supports this picture.

The low gas velocities may also be consistent with disrupted stellar gas on an elliptical orbit in a nascent disk, near the apocentre. This picture naturally gives a low filling factor, resulting in a small total mass in absorbing gas (see Methods). Recent numerical simulations predict that a fraction of the disrupted material in a TDE will circularize slowly13, and that flows will be filamentary27, while stellar gas that is more tightly bound can form an inner, Eddington-limited or super-Eddington disk more quickly.

The highly ionized, blueshifted gas discovered in our high-resolution X-ray spectra of ASASSN-14li confirms both fundamental and very recent theoretical predictions for the structure and evolution of TDEs. By pairing high-resolution X-ray spectroscopy with an ever-increasing number of TDE detections, it will become possible to test models of accretion disk formation and evolution, and to explore strong-field gravitation around massive black holes27.

METHODS

Estimates of prior black-hole luminosity. Using the ROSAT All-Sky Survey\(^1\), the region around the host galaxy, PGC043234, was searched for point sources. No sources were found. Points in the vicinity of the host galaxy were examined to derive a background count rate of 0.002 counts s\(^{-1}\). Assuming the Milky Way column density \(N_{H,MW}\) along this line of sight, and taking a typical Seyfert X-ray spectral index of \(\Gamma = 1.7\), this count rate translates into \(L = 4.8 \times 10^{42}\) ergs s\(^{-1}\). This limit is orders of magnitude below a Seyfert or quasar luminosity.

Optical/ultraviolet monitoring observations and data reduction. Swift\(^7\) monitors transient and variable sources via co-aligned X-ray (XRT, 0.3–10 keV) and ultraviolet–optical (UVOT, 170–650 nm) telescopes. High-cadence monitoring of ASASSN-14li with UVOT has continued in six bands: V, B, U, UVW1, UVM2, and UVW2 (central wavelength \(\lambda_c = 550\) nm, 440 nm, 350 nm, 260 nm, 220 nm, and 190 nm). All observations were processed using the latest HEASOFT (http://heasarc.gsfc.nasa.gov/docs/software/lheasoft/) suite and calibrations. Individual optical/ultraviolet exposures were astrometrically corrected and sub-exposures in each filter were summed. Source fluxes were then extracted from an aperture of 3\(^\circ\) radius, and background fluxes were extracted from a source-free region to the east of ASASSN-14li owing to the presence of a (blue) star lying 10 arcsec to the south. We estimated the uncertainty in each host flux by varying the inclusion aperture from 2\(^\circ\) to 4\(^\circ\).

We then fitted the host photometry to synthetic galaxy templates using the Fitting and Assessment of Synthetic Templates (FAST\(^6\)) code. We employed stellar templates from the\(^2\) catalogue, and allowed the star-formation history, extinction law, and initial mass function to vary over the full range of parameters allowed by the software. All best-fit models had stellar masses of about 10\(^8\) M\(_\odot\), low ongoing star-formation rates (at most about 10\(^{-1}\)–10\(^{-2}\) M\(_\odot\) yr\(^{-1}\)), and modest line-of-sight extinction (A\(_V\) \approx 0.4 mag).

We integrated the resulting galaxy template spectra over each UVOT filter bandpass to estimate the host count rate. For the uncertainty in this value, we adopt either the root-mean-square spread of the resulting galaxy template models, or 10\% of the inferred count rate, whichever value was larger. We then subtracted these values from our measured (coincidence-loss corrected) photometry of the host plus transient, to isolate the component that is due to TDE. For reference, our inferred count rates for each UVOT filter are 5.7 \pm 0.6 s\(^{-1}\) for V, 9.4 \pm 0.9 s\(^{-1}\) for B, 4.0 \pm 0.4 s\(^{-1}\) for U, 0.83 \pm 0.08 s\(^{-1}\) for UVW1, 0.29 \pm 0.03 s\(^{-1}\) for UVM2, and 0.49 \pm 0.05 s\(^{-1}\) for UVW2. Figure 1 shows the host-subtracted optical and ultraviolet light curves ASASSN-14li.

Fits to the Swift XRT and UVOT light curves. The UVM2 filter provides the most robust trace of the mass accretion rate in a TDE like ASASSN-14li; it has negligible transmission at optical wavelengths\(^3,4,5\). Fits to the UVW2 light curve with a power law of the form \(f(t) = f_0 (t + t_0)^{-\alpha}\) with a fixed index of \(\alpha = -5/3\) imply a disruption date of \(t_0 = 56,980 \pm 3\) (MJD). This model achieves a fair characterization of the data; high fluxes between days 80 and 100 (in the units of Fig. 1) result in a poor statistical fit (\(\chi^2 = 1.7\), where \(\chi^2 = n\cdot\sigma^2\) is the number of degrees of freedom). If the light curve is fitted with a variable index, a value of \(-2.6 \pm 0.3\) is measured (90\% confidence). This model achieves an improved fit (\(\chi^2 = 1.4\), for \(\chi^2 = 53\) degrees of freedom), but it does not tightly constrain the disruption date, placing \(t_0\) in the range 56,855–56,920 days. That disruption window is adjacent to an interval wherein the ASASSN-14li monitoring did not detect the source\(^4\), making it less plausible than the fit with \(\alpha = -5/3\).

The optical bands appear to have a shallower decay curve than the ultraviolet bands. Recent theory\(^7\) predicts that optical light produced via thermal disk emission should show a decay consistent with \(t^{-5/3}\); this might also be due to reprocessing. The V-band data are consistent with this prediction, though the data are of modest quality and a broad range of decay rates are permitted.

X-ray monitoring observations and data reduction. The Swift XRT\(^7\) is a charge-coupled device. In such cameras, photon pile-up occurs when two or more photons land within a single detection box during a single frame time. This causes flux distortions and spectral distortions to bright sources. Such distortions are effectively avoided by extracting events from an annular region, rather than from a circle at the centre of the telescope PSF. We therefore extracted source spectra from annuli with an inner radius of 12 arcsec (5 pixels), and an outer radius of 50 arcsec. Background flux was measured in an annular region extending from 140 arcsec to 210 arcsec. Standard redistribution matrices were used; an ancillary response file was created with the xrtmkarf tool (a routine within HEASOFT) using a vignetting corrected exposure map. The source spectra were rebinned to have 20 counts per bin with grppha. In all spectral fits, we adopted a lower spectral bound of 0.3 keV (36\%). The upper bound on spectral fits varied depending on the boundary of the last bin with at least 20 counts; this was generally around 1 keV (12\%). The XRT spectra were fitted with a model consisting of absorption in the Milky Way of a blackbody emitted at the redshift of the TDE, that is, \(\phi(z)\,\text{abs}(z)\,\text{body}(z)\), where \(N_\text{H} = 4 \times 10^{20}\) cm\(^{-2}\) and \(z = 0.0206\). The evolution of the best-fit temperature of this blackbody component is displayed in Fig. 3.

The blackbody temperature values measured from the Swift XRT are slightly higher (\(kT > 7–10\) eV) than those measured with XMM-Newton and Chandra. If an outflow component with fiducial parameters is included in the spectral model anyway, the XRT temperatures are then in complete agreement with those measured using XMM-Newton and Chandra.

Estimates of the black-hole mass. Luminosity values inferred for the band over which the high-resolution spectra are actually fitted, and for a broader band, are listed in Table 1. Taking the broader values as a proxy for a true bolometric fit, the highest implied soft X-ray luminosity is measured in the last XMM-Newton monitoring observation, giving \(L_\text{soft} \approx 3.2 \times 10^{44}\) ergs s\(^{-1}\). The Eddington luminosity for standard hydrogen-rich accretion is \(L_\text{Edd,HB} = 1.3 \times 10^{44}\) ergs s\(^{-1}\) (M\(_\odot\)). This implies a black-hole mass of \(M = 2.5 \times 10^6\) M\(_\odot\).

Blackbody continua imply size scales, and, if we assume that optically thick blackbody emission can only originate at radii larger than the innermost stable circular orbit (ISCO), also masses. For a non-spinning Schwarzschild black hole, \(r_{\text{ISCO}} = 6GM/c^2\). The blackbody emission measured in fits to the time-averaged XMM-Newton ‘long stare’ gives an emitting area of 3.7 \times 10^9 cm\(^2\), implying \(r = 1.7 \times 10^5\) cm for a spherical geometry. The actual geometry may be more disk-like, but the inner flow may be a thick disk that is better represented by a spherical geometry. If the black hole powering ASASSN-14li is not spinning, this size implies a black-hole mass of \(M = 1.9 \times 10^8\) M\(_\odot\).

We also estimated the mass of the black hole at the heart of ASASSN-14li by fitting the host-subtracted light curves (see Fig. 1) using the Monte Carlo software TDEFit\(^\text{\textsuperscript{1}}\). This software assumes that emission is produced within an elliptical accretion disk where the mass accretion rate follows the fallback rate\(^\text{\textsuperscript{3}}\) onto the black hole with a viscous delay\(^\text{\textsuperscript{2}}\). This emission is then partly reprocessed into the ultraviolet/optical part of the spectrum by an optically thick layer\(^\text{\textsuperscript{2}}\). Super-Eddington accretion is treated by presuming that a fitted fraction of the Eddington excess is converted into light that is reprocessed by the same optically thick layer. This excess can be produced either with an unbound wind\(^\text{\textsuperscript{3}}\), or with the energy deposited by shocks in the circularization process\(^\text{\textsuperscript{3}}\).

The software performs a maximum-likelihood analysis to determine the combinations of parameters that reproduce the observed light curves. We utilize the ASASSN, UVOT and XRT data in our light-curve fitting; the most likely models produce good fits to all bands simultaneously. Within the context of this TDE model, a black-hole mass of (0.4–1.2) \times 10^6 M\(_\odot\). (1σ) is derived.

Spectroscopic observations, data reduction and analysis. The optical spectra were analysed using the SPEX suite version 2.06 (ref. 20). The fitting procedure minimized a \(\chi^2\) statistic. The spectra are most sensitive in the 18–35 Å band, and all fits were restricted to this range. Within SPEX, absorption from the interstellar medium in the Milky Way was modelled using the model ‘hot’; a separate ‘hot’ component was included to allow for interstellar medium (ISM) absorption within PGC043234 at its known redshift (using the reis component in SPEX). The photoionized outflow was modelled using the pion component within the SPEX suite. The pion\(^\text{\textsuperscript{20}}\) includes numerous lines from intermediate charge states that are lacking in similar astrophysics packages. The fits explored in this analysis varied the gas column density (\(N_{\text{H,TD}}\)), the ionization parameter (\(\xi\), where \(\xi = L/4\pi r^2\)) and \(L\) is luminosity, \(n\) is the hydrogen number density and \(r\) is the distance between the...
There is weak evidence of emission lines in the spectra, perhaps with a P Cygni wavelength scale is 6 mA˚. At 18 A˚ this corresponds to a velocity of 100 km s$^{-1}$. According to an published paper, this is a small value, plausible either for a clumpy wind or gas; these were taken from our fits with pion. We included the resulting emission component in experimental fits to the XMM-Newton ‘long stare’. The best-fit model gives an emission measure of $(1.0 \pm 0.3) \times 10^{41}$ cm$^{-3}$, a redshift (relative to the host) of $270 \pm 130$ km s$^{-1}$, and an ionization parameter of $log_{10} \xi = 4.1 \pm 0.1$. According to an F-test, the emission component is only required at the 3σ level; however, it has some compelling properties. Combined with the blueshifted absorption spectrum, the redshifted emission gives P Cygni profiles. For the gas density of $n = 2 \times 10^{12}$ cm$^{-3}$ derived previously, the emission measure gives a radius of about 10$^{15}$ cm, comparable to the size scale inferred from absorption variability.

The strongest lines predicted by the emission model include He-like O VIII and H-like charge states of C, N and O. This model does not account for other emission line-like features in the spectra, which are more likely to be artefacts from spectral binning, or calibration or modelling errors. Emission features in the O K-edge region may be real, but caution is warranted. Other features are more easily discounted given that they differ between the RGS1 and RGS2 spectra.

### Code availability

All of the data reduction and spectroscopic fitting routines and packages used in this work are publicly available. The light-curve modelling package, TDEFit', is proprietary at this time owing to ongoing code development; a public release is planned in the coming year.

Formally, the mass outflow rate in ASASSN-14li can be adapted from the case where the density is known, and written as:

$$M_{\text{out}} = \mu n_{p} \Omega \rho v_{r} \zeta^{-1}$$

where $\mu$ is the mean atomic weight ($\mu = 1.23$ is typical), $n_{p}$ is the mass of the proton, $\Omega$ is the covering factor (0 ≤ $\Omega$ ≤ 4π), $L$ is the luminosity, $v_{r}$ is the outflow velocity, $C_{r}$ is the line-of-sight global (volume) filling factor and $\zeta$ is the ionization parameter. Using the values obtained in fits to the XMM-Newton ‘long stare’ (see Fig. 1), for instance, $M_{\text{out}} = 7.9 \times 10^{32} \Omega / C_{r} \mu$ g s$^{-1}$. Taking the value of $C_{r}$, derived above, an outflow rate of $M_{\text{out}} = 1.5 \times 10^{31}$ g s$^{-1}$ results. The kinetic power in the outflow is given by $L_{\text{kin}} = 0.5 \mu \Omega v_{r}^{2}$; using the same values assumed to estimate the mass outflow rate, $L_{\text{kin}} = 3.3 \times 10^{41}$ erg s$^{-1}$.

### Emission from the diffuse outflow

We synthesized a plausible wind emission spectrum by coupling the pion and hydro models within SPEX. The hydro code enables spectra to be constructed based on the output of hydrodynamical simulations. As inputs, the hydro code requires the electron temperature and ion concentrations for a gas; these were taken from our fits with pion. We included the resulting emission component in experimental fits to the XMM-Newton ‘long stare’. The best-fit model gives an emission measure of $(1.0 \pm 0.3) \times 10^{41}$ cm$^{-3}$, a redshift (relative to the host) of $270 \pm 130$ km s$^{-1}$, and an ionization parameter of $log_{10} \xi = 4.1 \pm 0.1$.
