Abstract

We describe a nonlinear interferometric setup to perform a complete optical Bell measurement, i.e. to unambiguously discriminate the four polarization-entangled EPR-Bell photon pairs. The scheme is robust against detector inefficiency.

1 Introduction

Entanglement and entangled states are fundamental concepts of the new field of quantum information [1]. They can be exploited for example in super-dense coding [2] or teleportation [3] both of which have been demonstrated experimentally. The most important example of entangled states is perhaps given by the four polarization-entangled Bell states involving two photons

\begin{align}
|\Psi_\pm\rangle &= \frac{1}{\sqrt{2}} \left[ |1001\rangle \pm |0110\rangle \right] = \frac{1}{\sqrt{2}} \left[ a_\parallel b_\perp \pm a_\perp b_\parallel \right]^\dagger |0\rangle , \\
|\Phi_\pm\rangle &= \frac{1}{\sqrt{2}} \left[ |1010\rangle \pm |0101\rangle \right] = \frac{1}{\sqrt{2}} \left[ a_\parallel b_\parallel \pm a_\perp b_\perp \right]^\dagger |0\rangle ,
\end{align}

where $a_\parallel (b_\parallel)$ denotes horizontal polarized and $a_\perp (b_\perp)$ denotes vertical polarized photons in the two possible directions of propagation denoted by $a$ and $b$ (see also Fig. 1). Indeed, these states have been produced experimentally via the nonlinear process of spontaneous down-conversion [4]. In order to actually

\textsuperscript{1} Corresponding author. E-mail address: Matteo.Paris@pv.infn.it
exploit entanglement, in the manipulation of quantum information one has to be able to distinguish the different maximally entangled states given above. This ability is crucial for the unambiguous experimental realization for example of quantum teleportation [3], where an unknown quantum state can be exchanged between two parties as long as they share an entangled state, and perform the appropriate measurement to discriminate it among the others.

A simple interferometric setup cannot be of help for the discrimination among the four EPR states, as it has been shown recently [5,6] that a complete Bell measurement cannot be performed using only linear elements. A method to overcome this conclusion has been suggested in Ref. [7], which, however, requires to embed the state of interest in a larger Hilbert space, and therefore can be applied only in presence of multiple entanglement (entanglement in more than two degrees of freedom).

2 Bell discrimination

In this paper we consider the nonlinear interferometric setup depicted in Fig. 1. Our starting point is a reliable source of optical EPR-Bell states, i.e., polarization entangled photon pairs. This is usually a birefringent crystal where type-II parametric down-conversion transforms an incoming pump photon into a pair of correlated ordinary and extraordinary photons. We assume that each pulse (the signal) is prepared in one of the four EPR-Bell states, and we want to unambiguously infer from measurements which one was actually impinging onto the apparatus.

The signal first enters a polarizing beam splitter, which transmits photons with a given polarization (say vertical) and reflects photons with the orthogonal one (say horizontal). The mode transformations of this element is given by (the notation for the field modes refers to Fig. 1 hereafter)

\[
\left( c_\parallel, c_\perp, d_\parallel, d_\perp \right) = \hat{U}_{\text{PBS}} \left( a_\parallel, a_\perp, b_\parallel, b_\perp \right) \hat{U}_{\text{PBS}}^\dagger = \left( b_\parallel, a_\perp, a_\parallel, b_\perp \right),
\]

and the corresponding Schrödinger evolution of the Bell states is

\[
\hat{U}_{\text{PBS}} \left( \Phi_+, \Phi_-, \Psi_+, \Psi_- \right) = \left( \Phi_+, \Phi_-, \chi_+, \chi_- \right).
\]

In Eq. (4) \( \chi_{\pm} \) are superpositions of states with both photons in the same path (arm)

\[
|\chi_{\pm}\rangle = \frac{1}{\sqrt{2}} \left[ |1100\rangle \pm |0011\rangle \right] = \frac{1}{\sqrt{2}} \left[ b_\parallel b_\perp \pm a_\parallel a_\perp \right]|0\rangle.
\]
Fig. 1. Schematic diagram of the nonlinear interferometric setup for the discrimination of the four Bell states. One of the four Bell states is produced at the "Bell Factory" (BF) and then impinges onto a polarizing beam splitter, whose action is to transmit photons with a fixed polarization (say vertical) and to reflect photons with the orthogonal one (say horizontal). Inside the interferometer the polarization of the photons in one arm is rotated (PR) by a half wave plate, whereas in the other arm a non-demolition measurement of the photon number is performed by means of a "Fock Filter" (FF) based on Kerr nonlinear interaction. Finally, the photons are recombined by an usual, not polarizing, balanced beam splitter (BS) and then revealed by a couple of avalanche single-photon photo-detectors. A coincidence circuit (CC) tells us whether the photons arrived one for each path or both packed in the same one. The field modes $c, d, e$ and $f$ are the Heisenberg evolute of the input field modes $a$ and $b$. Their explicit expressions are given in the text. The inset table describes the reaction of the two measurement stages (the Fock Filter FF and the coincidence circuit CC) to the presence of the four Bell states respectively.

The two sets of states, $\chi_\pm$ and $\Phi_\pm$, can now be discriminated by the number of photons travelling in one arm of the interferometer, which is either zero or two for $\chi_\pm$ and (certainly only) one for $\Phi_\pm$. Such a discrimination can be performed by means of a Fock Filter (FF), which is a novel kind of all-optical nonlinear switch [8]. Let us postpone the detailed description of the FF to section 3. For the moment we assume that it switches on when a single photon (of any polarization) is present, and does not switch for zero or more than one photons. As we will see, the FF performs a kind of non-demolition measurement of the photon number, such that coherence is preserved and the state after the measurement is still available for further manipulations. Indeed, the remaining part of the device should be able to distinguish phases, namely to discriminate between $\chi_+ \pm$ and $\chi_- \pm$, or between $\Phi_+ \pm$ and $\Phi_- \pm$. For this purpose, first the polarization of photons in the second arm is rotated by $\pi/2$ using a half-wave plate, thus turning $\Phi_\pm$ into $\Psi_\pm$ respectively, while leaving $\chi_\pm$ untouched. In fact, the transformation induced by the polarization rotator reads $\hat{U}_{PR} = I \otimes \hat{V}_{PR}$, where $\hat{V}_{PR}$ acts only on two modes.
\[(d'_\parallel, d'_\perp) = \hat{V}_{PR} (d_\parallel, d_\perp) \hat{V}^\dagger_{PR} = (d_\perp, -d_\parallel) \]  \hspace{1cm} (6)

and thus

\[\hat{U}_{PR} (\chi_+, \chi_-, \Phi_+, \Phi_-) = (\chi_+, \chi_-, \Psi_+, -\Psi_-) \]  \hspace{1cm} (7)

The two paths are then recombined into a balanced (not polarizing) beam splitter, whose action on generic field modes \(x\) and \(y\) is described by

\[\hat{U}_{BS} (x_\parallel, x_\perp, y_\parallel, y_\perp) \hat{U}^\dagger_{BS} = \frac{1}{\sqrt{2}} (x_\parallel + y_\parallel, x_\perp + y_\perp, x_\parallel - y_\parallel, x_\perp - y_\perp) \]  \hspace{1cm} (8)

If the transformation (8) is applied to the field modes \(c\) and \(d'\) we have, using Eqs. (6) and (3),

\[\begin{align*}
(e_\parallel, e_\perp, f_\parallel, f_\perp) &= \hat{U}_{BS} (c_\parallel, c_\perp, d'_\parallel, d'_\perp) \hat{U}^\dagger_{BS} \\
&= \frac{1}{\sqrt{2}} (c_\parallel + d'_\parallel, c_\perp + d'_\perp, c_\parallel - d'_\parallel, c_\perp - d'_\perp) \\
&= \frac{1}{\sqrt{2}} (b_\parallel + b_\perp, a_\perp - a_\parallel, b_\parallel - b_\perp, a_\perp + a_\parallel) .
\end{align*} \hspace{1cm} (9)

In terms of the state just before the BS this corresponds to the following Schrödinger evolution

\[\hat{U}_{BS} (\chi_+, \chi_-, \Psi_+, \Psi_-) = (\chi_+, \Psi_+, \chi_-, -\Psi_-) \]  \hspace{1cm} (10)

Finally, the photons are measured by single-photons avalanche photo-detectors, where the last stage of the setup is a coincidence circuit (CC). In fact, \(\Psi_\pm\) correspond to the presence of photons in both channel, whereas \(\chi_\pm\) are superpositions with both photons in the same path. In terms of the states before the BS, this means that superpositions with the minus sign (\(\chi_-\) and \(\Psi_-\)) lead to coincident clicks at photo-detectors (CC ON), whereas superpositions with the plus sign (\(\chi_+\) and \(\Psi_+\)) do not switch on the coincidence circuit.

The whole chain of transformations of our setup can be summarized by the following diagram

\[
\begin{array}{ccccccccc}
\Phi_+ & \xrightarrow{PBS} & \Phi_+ & \xrightarrow{FF \ ON} & \xrightarrow{PR} & \Psi_+ & \xrightarrow{BS} & \Psi_- & \xrightarrow{CC \ ON} \\
\Phi_- & \xrightarrow{PBS} & \Phi_- & \xrightarrow{FF \ ON} & \xrightarrow{PR} & -\Psi_- & \xrightarrow{BS} & \Psi_- & \xrightarrow{CC \ ON} \\
\Psi_+ & \xrightarrow{PBS} & \chi_+ & \xrightarrow{FF \ OFF} & \xrightarrow{PR} & \chi_+ & \xrightarrow{BS} & \chi_+ & \xrightarrow{CC \ OFF} \\
\Psi_- & \xrightarrow{PBS} & \chi_- & \xrightarrow{FF \ OFF} & \xrightarrow{PR} & \chi_- & \xrightarrow{BS} & \Psi_+ & \xrightarrow{CC \ ON}
\end{array}
\]
which illustrates the unambiguous discrimination of the four Bell states.

Our scheme is minimal, as it involves only two measurements, and thus only four possible outcomes, which equals the number of states to be discriminated.

3 Fock Filtering

The Fock Filter is schematically depicted in Fig. 2. The signal under examination is coupled to a high-Q ring cavity by a nonlinear crystal with relevant third-order susceptibility $\chi \equiv \chi^{(3)}$, which imposes cross-Kerr phase modulation. We assume that the coupling is independent of polarization, such that the evolution operator of the Kerr medium is given by

$$U_K = \exp \left\{ -ig(a_\parallel^\dagger a_\parallel + a_\perp^\dagger a_\perp)c^\dagger c \right\},$$

where $g = \chi t$ is the coupling constant, the $a$’s are the two polarization modes of the signal, and $c$ describes the cavity mode. Eq. (11) states that, as a result of the Kerr interaction, the cavity mode is subjected to a phase-shift proportional to the number of photons passing through the arm of the interferometer. The FF is complemented by a further, tunable, phase-shift $\psi$, and operates with the ring cavity fed by a strong coherent state $|z\rangle$, i.e. a weak laser beam provided by a stable source (the second port of the cavity is left unexcited). The input state of the whole device can be written as $|\varphi_{in}\rangle = |z\rangle|0\rangle|\nu\rangle$, where $|\nu\rangle = \sum n_\perp n_\parallel |n_\perp\rangle|n_\parallel\rangle$ denotes a generic preparation of the signal mode. The output state is given by

![Fig. 2. Schematic diagram of the Fock Filter. The signal modes are coupled to the cavity mode by a nonlinear crystal with relevant third-order susceptibility $\chi^{(3)}$. The resulting cross-phase modulation imposes to the cavity mode a phase-shift proportional to the number of photons of the signal. The ring cavity is built by the mirrors $M_1$ and $M_2$, and by the low transmittivity beam splitters $BS_1$ and $BS_2$, whereas $\psi$ denotes an externally tunable phase-shift. The cavity is fed by a strong coherent state $|z\rangle$, and its output is monitored by an avalanche photo-detector.](image-url)
\[ |\varphi_{\text{out}}\rangle = \sum_{n_{\perp} n_{\parallel}} \nu_{n_{\perp} n_{\parallel}} |\sigma_{n_{\perp} + n_{\parallel}} z\rangle |\kappa_{n_{\perp} + n_{\parallel}} z\rangle |n_{\perp})|n_{\parallel}\rangle, \]  

where

\[ \sigma_n = \frac{\tau}{1 - [1 - \tau] e^{i \phi_n}}, \quad \kappa_n = \frac{\sqrt{1 - \tau (e^{i \phi_n} - 1)}}{1 - [1 - \tau] e^{i \phi_n}}, \]  

are the overall photon-number-dependent transmitivity and reflectivity of the cavity. In Eq. (13) \( \phi_n = \psi - gn \), whereas \( \tau \) denotes the transmitivity of the cavity beam splitters \( BS_1 \) and \( BS_2 \). For a good cavity, (i.e. a cavity with large quality factor) \( \tau \) should be quite small, usual values achievable in quantum optical labs are about \( \tau \approx 10^{-4} - 10^{-6} \) (losses, due to absorption processes, are about \( 10^{-7} \)). At the cavity output one mode is ignored, whereas the other one is monitored by an avalanche single-photon photo-detector, which checks whether or not photons are present. This kind of \textit{ON/OFF} measurement is described by a two valued POM

\[ \hat{\Pi}_{\text{OFF}} = \sum_k (1 - \eta)^k |k\rangle \langle k| \quad \hat{\Pi}_{\text{ON}} = 1 - \hat{\Pi}_{\text{OFF}}, \]

\( \eta \) being the quantum efficiency of the photo-detector. If the state travelling through the interferometer is either \( \Phi_+ \) or \( \Phi_- \) we have \( |\varphi_{\text{in}}\rangle = |z\rangle |0\rangle |\Phi_{\pm}\rangle \) and thus

\[ |\varphi_{\text{out}}\rangle = \frac{1}{\sqrt{2}} \left[ |\sigma_1 z\rangle |\kappa_1 z\rangle |1010\rangle \pm |\sigma_1 z\rangle |\kappa_1 z\rangle |0101\rangle \right] = |\sigma_1 z\rangle |\kappa_1 z\rangle |\Phi_{\pm}\rangle. \]  

The probability of having a click is given by

\[ P(\text{ON}|\Phi_{\pm}) = \text{Tr} \left\{ |\varphi_{\text{out}}\rangle \langle \varphi_{\text{out}}| \hat{\Pi}_{\text{ON}} \right\} = 1 - \exp \left( -\eta |\sigma_1 z|^2 \right), \]

whereas the conditional output signal state, after a click has been actually registered, turns out to be

\[ \hat{\nu}_{\text{out}}(\text{ON}|\Phi_{\pm}) = \frac{1}{P(\text{ON}|\Phi_{\pm})} \text{Tr}_{\text{cavity}} \left\{ |\varphi_{\text{out}}\rangle \langle \varphi_{\text{out}}| \hat{\Pi}_{\text{ON}} \right\} = |\Phi_{\pm}\rangle \langle \Phi_{\pm}|. \]

By setting \( \psi = g \) and for \( \eta |z|^2 \gg 1 \) we have \( P(\text{ON}|\Phi_{\pm}) \approx 1 \). On the other hand, if the signal is either \( \chi_+ \) or \( \chi_- \) we have \( |\varphi_{\text{in}}\rangle = |z\rangle |0\rangle |\chi_{\pm}\rangle \) and

\[ |\varphi_{\text{out}}\rangle = \frac{1}{\sqrt{2}} \left[ |\sigma_2 z\rangle |\kappa_2 z\rangle |1100\rangle \pm |\sigma_0 z\rangle |\kappa_0 z\rangle |0011\rangle \right] \]
\[ \frac{1}{\sqrt{2}} \left[ |\sigma z\rangle|\kappa z\rangle|1100\rangle \pm |\sigma^* z\rangle|\kappa^* z\rangle|0011\rangle \right], \quad (18) \]

where the second equality comes from the fact that by setting \( \psi = g \) we have \( \sigma_0^* = \sigma_2 \equiv \sigma \). Finally, from Eqs. (14) and (18) we have

\[ P(\text{OFF}|\chi_{\pm}) = \exp \left( -\eta |\sigma|^2 |z|^2 \right) \quad (19) \]

\[ \hat{\nu}_{\text{out}}(\text{OFF}|\chi_{\pm}) = |\chi_{\pm}\rangle\langle \chi_{\pm}|. \quad (20) \]

For small \( g \) and \( \tau \) we have \( |\sigma|^2 \simeq (\tau/g)^2 \). Therefore, for \( \tau \ll g \) we have \( P(\text{OFF}|\chi_{\pm}) \simeq 1 \). This means that a click at the Fock Filter unambiguously implies that either \( \Phi_+ \) or \( \Phi_- \) was travelling through the interferometer, where having no click indicates the passage of either \( \chi_+ \) or \( \chi_- \). Remarkably, the measurement is quite robust against detector inefficiency (as only the product \( \eta |z|^2 \) is relevant) and does not destroy coherence. For both the possible outcomes (either \text{ON} or \text{OFF}) the state after the measurement remains unaffected, and is still available for further manipulations.

4 Conclusions

In conclusion, we have described an interferometric setup to perform a complete optical Bell measurement. It consists of a Mach-Zehnder interferometer with the first beam splitter a polarizing one, and the second a normal one, and where inside the interferometer a non-demolition photon number measurement is performed by the Fock filtering technique. The resulting scheme is robust against detectors inefficiency, and provides a reliable method to unambiguously discriminate among the four polarization-entangled EPR-Bell photon pairs.
