An improved U(1) slave-boson approach is applied to study the optical conductivity of the two dimensional systems of antiferromagnetically correlated electrons over a wide range of hole doping and temperature. Interplay between the spin and charge degrees of freedom is discussed to explain the origin of the peak-dip-hump structure in the in-plane conductivity of high $T_C$ cuprates. The role of spin fluctuations of short range order (spin singlet pair) is investigated. It is shown that the spin fluctuations of the short range order can cause the mid-infrared hump, by exhibiting a linear increase of the hump frequency with the antiferromagnetic Heisenberg coupling strength.

High $T_C$ superconductors are the systems of strongly correlated electrons which show two dimensionality in charge transport. Various levels of gauge theoretic slave-boson approach to t-J Hamiltonian have been proposed to study high $T_C$ superconductivity. Recently we proposed an SU(2) slave-boson theory which incorporated coupling between the charge and spin degrees of freedom into the Heisenberg term. The predicted phase diagram showed an arch-shaped bone condensation line in agreement with observation. Using an improved U(1) slave-boson theory over our earlier one, in this paper we study the cause of peak-dip-hump structures of observed optical conductivity. Various theories have been proposed to explain the cause of the peak-dip-hump structure in the optical conductivity. However, most studies have been made to a limited range of hole doping and temperature, based on empirical parameters deduced from measurements such as the inelastic neutron scattering (INS) and the angle resolved photoemission spectroscopy (ARPES) data.

Using the nearly antiferromagnetic Fermi-liquid theory, Stojković and Pines reported a study of normal state optical conductivity for optimally doped and overdoped systems. They showed that the highly anisotropic scattering rate in different regions of the Brillouin zone leads to an average relaxation rate of the marginal Fermi-liquid form. Their computed optical conductivity agreed well with experimental data for the normal state of an optimally doped sample. Using the spin-fermion model and spin susceptibility parameters obtained from INS and NMR, Munzar, Bernhard and Cardona calculated the in-plane optical conductivity of optimally doped YBCO. Their study showed a good agreement with the observed peak-dip-hump structure at optimal doping. From the computed self energy they showed that the hump is originated from the hot quasiparticles and the Drude peak, from the cold quasiparticles. Haslinger, Chubukov and Abanov reported optical conductivities $\sigma(\omega)$ of optimally doped cuprates in the normal state by allowing coupling between the spin-fermions and the bosonic spin fluctuations. They found that the width of the peak in spectral function $A_k(\omega)$ scales linearly with $\omega$ in both hot and cold spots in the Brillouin zone and $\sigma(\omega)$ is inversely linear in $\omega$ up to very high frequencies.

Various studies have been limited to a restricted range of hole doping and temperature, relying on empirical parameters deduced from INS and ARPES. It is thus of great interest to resort to a theory which depends least on empirical parameters and fits for a wide range both of hole doping (including the important region of underdoping) and temperature (encompassing the pseudogap phase and the superconducting phase). For this cause we use an improved slave-boson theory of the t-J Hamiltonian that we developed recently.

Here we briefly discuss the slave-boson theory to discuss the coupling between the spin and charge degrees of freedom. The t-J Hamiltonian in the presence of the external electromagnetic field $\mathbf{A}$ is written

$$H = -t \sum_{<i,j>} (\epsilon^{\uparrow} c_{i\sigma}^{\dagger} \tilde{c}_{j\sigma} + H.C.) + J \sum_{<i,j>} (\mathbf{S}_i \cdot \mathbf{S}_j - \frac{1}{4} n_i n_j) - \mu \sum_{i,\sigma} c_{i\sigma} c_{i\sigma}, \quad (1)$$

with $\mathbf{S}_i = \frac{1}{2} \sum_{\alpha,\beta} c_{i\alpha}^{\dagger} \sigma_{\alpha\beta} c_{i\beta}$. Here $A_{ij}$ is the external electromagnetic vector potential; $\tilde{c}_{i\sigma} (c_{i\sigma}^{\dagger})$, the electron annihilation (creation) operator at each site and $\sigma_{\alpha\beta}$, the Pauli spin matrix. Rewriting the electron operator as a composite of spinon($f$) and holon($b$) operators, $c_{i\sigma} = f_{i\sigma} b_{i\sigma}^{\dagger}$ with the single occupancy constraint, $b_{i\sigma}^{\dagger} b_{i\sigma} + \sum_{\sigma} f_{i\sigma}^{\dagger} f_{i\sigma} = 1$, we obtain the partition function

$$Z = \int \mathcal{D}f \mathcal{D}b \mathcal{D}\lambda e^{-\int W d\tau}, \quad (2)$$

with $W = \sum_{i,\sigma} f_{i\sigma}^{\dagger} \partial_{\tau} f_{i\sigma} + \sum_{\sigma} b_{\sigma}^{\dagger} \partial_{\tau} b_{\sigma} + H_{t-J}$ where $H_{t-J}$ is the U(1) slave-boson representation of the above t-J Hamiltonian (Eq. (1)),

$$H_{t-J} = -t \sum_{<i,j>} (\epsilon^{\uparrow} A_{ij} f_{i\sigma}^{\dagger} f_{j\sigma} b_{i\sigma}^{\dagger} b_{j\sigma} + c.c.)$$
\[-\frac{J}{2} \sum_{<i,j>} b_i b_j b_i^\dagger (f_{i,j}^\dagger f_j^\dagger - f_{i,j}^\dagger f_{j,i}^\dagger) (f_{i,j} f_{j,i} - f_{j,i} f_{i,j}) \]
\[-\mu \sum_{i,\sigma} f_i^\dagger f_i^\sigma + i \sum_i \lambda_i (f_i^\uparrow f_i^\downarrow + b_i^\dagger b_i - 1). \quad (3)\]

This Hamiltonian can really be derived from the SU(2) theory \([12]\).

From the Hubbard-Stratonovich transformations involving hopping, spinon and holon pairing orders we obtain the partition function,
\[Z = \int Df D\delta \chi D\Delta f D\Delta \delta \lambda e^{-\int_0^\beta dr \mathcal{L}_{\text{eff}}}, \quad (4)\]
with \(\mathcal{L}_{\text{eff}} = \mathcal{L}^f + \mathcal{L}^b + \mathcal{L}_0\) is the Lagrangian where \(\mathcal{L}^f = \sum_{i,\sigma} f_i^\dagger \partial_r f_i^\sigma - \frac{J(1-\delta)^2}{4} \sum_{<i,j>} \left\{ \chi_{ij} f_i^\dagger f_j^\dagger f_{j,i} + H.C. \right\} - \frac{J(1-\delta)^2}{4} \sum_{<i,j>} \left\{ |\Delta_{ij}|^2 \frac{\delta f_{ij}^\dagger}{\lambda_{ij}} |\Delta_{ij}| + H.C. \right\}\) for the spinon sector, \(\mathcal{L}^b = \sum_i b_i^\dagger \partial_r b_i - \sum_{<i,j>} \left\{ e^{i\beta A_{ij}} \chi_{ij} b_i^\dagger b_j + H.C. \right\}\) for the holon sector and \(\mathcal{L}^b = J(1-\delta)^2 \sum_{<i,j>} \left\{ |\Delta_f^f|^2 + \frac{1}{4} |\chi_{ij}|^2 + \frac{1}{\lambda_{ij}} \right\}\) + \(\frac{J}{2} \sum_{<i,j>} \left| |\Delta_f^f|^2 \right| \left| \Delta_{ij} \right|^2\). Here \(\chi, \Delta_f^f\) and \(\Delta_{ij}\) are the hopping, spinon pairing and holon pairing order parameters respectively.

We obtain the optical conductivity \(\sigma(\omega)\) and the current response function \(\Pi(\omega)\) of an isotropic 2-D medium in the external electric field \(\mathbf{E}(\omega)\) by evaluating the second derivative of the free energy with respect to the external vector potential \(\mathbf{A}\),
\[\sigma(\omega) = \frac{\partial J_x(\omega)}{\partial E_x(\omega)} \bigg|_{E_x=0} = -\frac{1}{\omega} \frac{\partial^2 F}{\partial A_x^2} \bigg|_{A_x=0} = \Pi_{1xx}(\omega) \frac{i\omega}{\omega}, \quad (5)\]
where \(J_x\) is the induced current in the x direction; \(F = -k_BT \ln Z\), the free energy and \(\Pi_{1xx} = -\frac{\partial^2 F}{\partial A_x^2} \bigg|_{A_x=0}\) the current response function in the x-direction. The total response function, \(\Pi = \Pi^f + \Pi^b\) is the sum of the paramagnetic response function given by the current-current correlation function \(\Pi^f(r'-r, t'-t) = -j_x(r', t')j_x(r, t) > < j_x(r', t') > < j_x(r, t) > \) with the current operator \(j_x(r, t) = \partial_r \chi_{ij} c_{r+i,\sigma}^\dagger c_{r,\sigma}(t) - c_{r+i,\sigma}(t) c_{r+i,\sigma}(t)\) and the diamagnetic response function associated with the average kinetic energy, \(\Pi^b = -K_{xx} = \left\langle -\left(\sum_{i,\sigma} (c_{i+x,\sigma}^\dagger c_{i+x,\sigma} + H.C.) \right) \right\rangle\) [13].

The phase difference per unit lattice spacing associated with the hopping order parameter \(\chi_{ij} = |\chi_{ij}| e^{a_{ij}}\) defines the gauge field, \(a_{ij} = \partial_j \theta - \partial_i \theta\). The gauge fluctuations allow the back-flow condition in association with an interplay between the charge and spin degrees of freedom originated from the effective kinetic energy term of the t-J Hamiltonian. The effects of spin degrees of freedom are manifested through the antiferromagnetic spin fluctuations which appear in the Heisenberg exchange coupling term. The antiferromagnetic spin fluctuations of short range order/spin singlet pair) occur through the presence of correlations between adjacent electron spins. We consider both the amplitude fluctuations of the spin pairing/spin singlet order parameter \(|\Delta_f^f|\) and the gauge field fluctuations. We first integrate out the spinon and holon fields and take the saddle point value with respect to the holon pairing order parameter, spinon pairing order parameter phase, the amplitude of hopping order parameter and the Lagrangian multiplier fields in Eq.\(\mathcal{L}_0\). We then obtain,
\[F[A] = -k_BT \ln \int Df D\delta \chi D\Delta f D\Delta \delta \lambda e^{-\int_0^\beta dr \left( F^f + F^b + \mathcal{L}_0 \right)} \approx -k_BT \ln \int D\mathbf{A} \left| D\delta \chi \right| \left( e^{-\beta \left( F^f + \mathcal{L}_0 \right) + F^b[A, \mathbf{A}, \Delta_f^f]} \right) \times e^{F_0[A, \mathbf{A}, \Delta_f^f]} \right), \quad (6)\]
where \(F^f = -k_BT \int Df e^{-\int_0^\beta dr \mathcal{L}^f}\) is the spinon free energy, \(F^b = -k_BT \int D\delta \chi e^{-\int_0^\beta dr \mathcal{L}^b}\) the holon free energy and \(F_0 = -k_BT \ln e^{-\int_0^\beta dr \mathcal{L}_0}\). The external electromagnetic field couples only to the holon field but not to the spinon field.

Considering the gauge and antiferromagnetic spin fluctuations up to second order we obtain the current response function,
\[\Pi = \frac{\Pi^f \Pi^b}{\Pi^f + \Pi^b} + \frac{\left( \Pi_{1xx}^f - \Pi_{1xx}^b + \Pi^f \Pi^b \Pi_{1xx}^b \right)^2}{2 \left( \Pi^f + \Pi^b \right)^2 - \left( \Pi_{1xx}^f + \Pi_{1xx}^b \right)^2 - \left( \Pi_{1xx}^b + \Pi^b \Pi_{1xx}^b \Pi^f \Pi^b \right)^2}, \quad (7)\]
where \(\Pi^f(\Pi^b)\) is the spinon(holon) response function associated with the gauge field \(\mathbf{a}(\mathbf{a})\) and \(\mathbf{A}(\mathbf{A})\); \(\Pi_{XY} = -\frac{\partial^2 F}{\partial A_x \partial A_y}\) the (spinon(holon)) response function associated with both the gauge fields and the spin pairing field and \(\Pi_{1xx}^f\), the response function associated with the spinon pairing field. It is shown that the first term represents the Ioffe-Larkin rule [12] for the current response function contributed only from the gauge field fluctuations, and the second term, from the spin fluctuations. Each contribution comes from the coupling between the charge and spin degrees of freedom, as manifested by Eq.\(\mathcal{L}_0\).

The response function \(\Pi^f(\Pi^b)\) is contributed from both the paramagnetic and diamagnetic parts. The paramagnetic response function is obtained from the current-current correlation functions \(\Pi_{1xx}^f(P) = < j_x^f(r', t') j_x^f(r, t) > < j_x^f(r', t') > < j_x^f(r, t) > \) for the spinon and \(\Pi_{1xx}^b(P) = < j_x^b(r', t') j_x^b(r, t) > < j_x^b(r', t') > < j_x^b(r, t) > \) for the holon, and the diamagnetic response function involves the average kinetic energy of spinon(holon). \(\Pi_{1xx}^f(\Pi_{1xx}^b)\) is given by the correlations between the spinon(holon) current and the 'anomalous' spinon(holon) pairing, \(\Pi_{1xx}^f = < j_x^f(r', t') D_f^f(r, t) > < j_x^f(r', t') D_f^f(r, t) > < D_f^f(r, t) > < \Pi_{1xx}^f > < j_x^b(r', t') D_b^b(r, t) > < j_x^b(r', t') D_b^b(r, t) > < D_b^b(r, t) > < \Pi_{1xx}^b > < \Pi_{1xx}^f > < \Pi_{1xx}^b > \left( \sum_l \left( e^{-\beta \mathbf{r}_f^b(t)} \mathbf{r}_f^b(t) \right) + H.C. \right) \) and \(D_b^b(r, t) \sim \sum_l (b_l r_l b_{r+l} + H.C.)\). Here \(l\) represents
nearest neighbor sites around location \( r \) and \( \tau = \pm \frac{2t}{\hbar} (\pm -) \) for \( x(y) \)-direction is a phase to represent the spinon pairing of d-wave symmetry. \( \Pi_{\Delta \Delta} \) represents correlations between pairing currents: \( \Pi^\Delta_{\Delta \Delta} = \langle D^\dagger (r', t') D^\dagger (r, t) \rangle - \langle D^\dagger (r', t') \rangle \langle D^\dagger (r, t) \rangle \) for the spinon pairs and \( \Pi^\Pi_{\Delta \Delta} = \langle D^b (r', t') D^b (r, t) \rangle - \langle D^b (r', t') \rangle \langle D^b (r, t) \rangle \rangle \) for the holon pairs.

Fig. 2 shows computed optical conductivities from the U(1) slave-boson t-J Hamiltonian(Eq. (3)) with \( J=0.3t \) for the underdoped\( (\delta = 0.05) \), optimally doped\( (\delta = 0.07) \) and overdoped\( (\delta = 0.1) \) regions. Compared to the present U(1) result of optimal doping the SU(2) slave-boson theory [6] predicted a more realistic value of optimal doping close to \( \delta \approx 0.15 \), by yielding a phase diagram of showing an arch shaped boson condensation temperature in better agreement with observation. To avoid complexity, we resort to the simpler case of U(1) as our prime interest lies in the investigations of the role of spin fluctuations and the coupling between the charge and spin degrees of freedom on the formation of peak-dip-hump structures, since the accurate SU(2) theory will not alter physics on the cause of the peak-dip-hump structure. Although not shown here for other values of \( J \) we find qualitative agreements with experiments in that the peak-dip-hump structures are well predicted below \( T^* \) and \( T_C \). In Fig. 2 the hump peak position is seen to remain nearly constant with the variation of hole doping and temperature below \( T^* \) but not so above \( T_C \). In general, the predicted hump position tends to shift to a lower frequency with increasing hole concentration and with temperature, showing a gradual disappearance of the hump. A trend of rapid drop in a high frequency region is seen to be unrealistic. In order to find the role of spin fluctuations, we neglected the second term in Eq. (3). The hump structure(dotted line in Fig. 2) completely disappeared, clearly indicating that spin-spin correlations or spin fluctuations associated with the spin singlet excitations are responsible for the hump formation in the optical conductivity(Fig. 3). For an additional analysis of spin fluctuations we computed the optical conductivity using the Lanczos exact diagonalization method for a two hole doped \( 4 \times 4 \) lattice by introducing various Heisenberg antiferromagnetic coupling strength \( J \). Despite the finite size effects an irregular but gross feature of peak-dip-hump structure is still predicted indicating that the hump is originated from the spin-spin correlations. A linear increase in the hump position with \( J \) is predicted. From both the slave-boson and Lanczos calculations we note that the peak locations of the hump are sensitive to the variation of the antiferromagnetic coupling strength \( J \), by showing a linear increase. Further, as mentioned above the neglect of the spin fluctuations(the second term in Eq. (3)) led to a sudden disappearance of the hump structure.

Although not shown here, using the present U(1) slave-boson theory the predicted spectral functions around \((\pi, 0)\) point in momentum space also showed the peak-dip-hump structure consistent with ARPES data. This incoherent background or the hump around the \((\pi, 0)\) point was found to occur as a result of the antiferromagnetic spin fluctuations, having a common feature with the hump structure of the optical conductivity. Thus we conclude from these multifaceted studies that the spin-spin correlations or the spin fluctuations involved with electrons around the \((\pi, 0)\) point in momentum space are definitely the prime cause of the hump structures below \( T^* \) and \( T_C \).

In the present study, by paying attention to a wide range of both hole doping(under-, optimal and over-doping) and temperature\( (T < T_C, T_C < T < T^*, \text{and } T^* < T) \) with no empirical parameters obtained from measurements, we examined the optical conductivity as a function of frequency for the two-dimensional systems of strongly correlated electrons. Allowing the coupling between the spin and charge degrees of freedom as manifested in Eq. (7), the peak-dip-hump structures are predicted in agreement with observations. It is shown that the antiferromagnetic spin fluctuations of short range associated with the spin singlet pair excitations are important in yielding the observed hump structure, and that the hump position linearly increase with the antiferromagnetic Heisenberg coupling strength. In general, the predicted peak-dip-hump structures are in good agreement with observations particularly in the temperature ranges of \( T < T_C \) and \( T_C < T < T^* \) for the underdoped case. It is shown that the spin fluctuations of the shortest possible antiferromagnetic correlation length(that is the spin singlet pair) alone can cause the formation of the hump structure. However, considerations of both the antiferromagnetic spin fluctuations of correlation lengths larger than the spin singlet pair and the direct channel single spin fluctuations at high energies may be needed to remedy quantitative discrepancies in the rapid drops of optical conductivity at temperatures above \( T^* \) and at frequencies beyond the peak location of the hump.
