Abstract: Adding fibers is highly effective to enhance the deflection and ductility of fiber-reinforced polymer (FRP)-reinforced beams. In this study, the stress and strain conditions of FRP-reinforced lightweight aggregate concrete (LWC) beams with and without fibers at ultimate load level were specified. Based on the sectional analyses, alternative equations to predict the balanced reinforcement ratio and flexural capacity for beams failed by balanced failure and concrete crushing were established. A rational equation for estimating the short-term stiffness of FRP–LWC beams at service-load levels was suggested based on Zhu's model. In addition, the contribution of the steel fibers on the short-term stiffness was quantified incorporating the effects of FRP reinforcement ratio. The proposed short-term stiffness model was validated with measured deflections from an experimental database for fiber-reinforced normal weight concrete (FNWC) beams reinforced with FRP bars. Furthermore, six glass fiber-reinforced polymer (GFRP)-reinforced LWC beams with and without steel fibers were tested under four-point bending. Based on the test results, the proposed models and procedures according to current design codes ACI 440.1R, ISIS-M03, GB 50608, and CSA S806 were linked together by comparing their predictions. The results showed that increasing the reinforcement ratio and adding steel fibers decreased the strain of the FRP bars. The flexural capacity of the LWC beams with and without steel fibers was generally underestimated by the design codes, while the proposed model provided accurate ultimate moment predictions. Moreover, the proposed short-term stiffness model yielded reasonable estimations of deflection for both steel fiber-reinforced lightweight aggregate concrete (SFLWC) and FNWC beams.

Keywords: fiber-reinforced polymer (FRP); lightweight aggregate concrete (LWC); steel fiber; balanced reinforcement ratio; ultimate moment; deflection

1. Introduction

Steel reinforcement corrodes rapidly when exposed. With the urgency of the sustainable infrastructure development and the innovation of structural system, fiber-reinforced polymer (FRP) bar has become increasingly applied in engineering construction as a substitute to conventional steel reinforcement, due to its lightweight, high tensile strength and non-corrosive properties [1–5]. On the other hand, the artificial lightweight aggregates constitute promising alternatives to natural aggregates due to their environmentally-friendly production process [6]. Moreover, the reduced mass of lightweight aggregate concrete (LWC) allows for a reduction in cross section and reinforcement amount in the concrete structural members, and thus exerts a favorable effect on both seismic resistance and economy [7]. In view of the characteristics of FRP and fiber-reinforced lightweight aggregate concrete (FLWC), their combined use could be beneficial not only in improving the strength-to-weight ratio, but also in decreasing the overall life cost of the structures [8].
FRP bars display linear elastic behavior in tension until failure and exhibit no yielding. Therefore, for FRP-reinforced concrete (FRP-RC) beams, the over-reinforced section design is recommended by most of the design codes [9,10], since the failure mode of concrete crushing is less catastrophic than FRP rupture. However, the strong brittleness of the LWC could bring adverse impacts on the ductility performance of the FRP-RC beams. Furthermore, the FRP-RC beams tend to experience large deflection due to the low elastic modulus of the FRP bars. The incorporation of fibers in concrete has been proved to be effective in enhancing the deflection and ductility performance altogether [11]. It should be mentioned that the use of steel fibers in FRP-RC beams was found to be valid because the corrosion of the steel fibers had a marginal effect on the performance of the members, even for high concentrations of chloride solutions [12].

Numerous research studies have been conducted on the prediction of ultimate moment and deflection of FRP-RC beams reinforced with steel fibers. Yang et al. [13] investigated the accuracy of ultimate capacity models based on test results of carbon fiber-reinforced polymer (CFRP)-reinforced beams with steel fibers and confirmed that the ultimate moment could be correctly estimated by ACI 544.4R and Campione when the ultimate concrete compressive strain was assumed as 0.004. Issa et al. [14] compared the test results of fibrous glass fiber-reinforced polymer (GFRP)-reinforced concrete beams to the available models and concluded that the ultimate moment capacity was strongly underestimated by ACI 440.1R, while the effective moment of inertia equation proposed by Faza and Ganga Rao [15] yielded the best deflection predictions through comparison. Yoo et al. [16] carried out flexural tests on ultra-high-performance fiber-reinforced concrete beams reinforced with GFRP bars, and modified the deflection model in ACI 440.1R considering the fiber reinforcement in the tensile zone after cracking.

Up to now, research concerning bearing capacity and deformation of FRP-reinforced beams fabricated using LWC, especially FLWC, was still limited. This paper aims to establish the balanced reinforcement ratio, ultimate moment and deflection equations of LWC beams with and without fibers.

2. Balanced Reinforcement Ratio and Ultimate Moment Model of FRP–FLWC Beams

2.1. Strain and Stress Conditions

The balanced failure refers to the failure mode in which the FRP tendons reach their ultimate tensile strain ($\epsilon_{fu}$) and the concrete reaches its ultimate compressive strain ($\epsilon_{cu}$) simultaneously. The corresponding reinforcement ratio is the balanced reinforcement ratio ($\rho_{fb}$), which is the theoretical demarcation point to identify the failure mode of FRP-RC flexural members. At maximum load levels, FRP-reinforced beams generally experienced significant flexural cracking, although the fibers were added in the concrete [13,17]. Considering the fact that the fibers were pulled out or ruptured in cracked section, the tensile loads could not be transferred across the cracks by the bridging of fibers. Therefore, it is assumed that the concrete tensile stress in pre-cracking tensile zone ($\gamma_{2}d$) distributes linearly, while concrete tensile strength in cracked section ($d(1 - \gamma_{1} - \gamma_{2})$) is ignored (Figure 1). In addition, the following assumptions are made for the calculation of the $\rho_{fb}$ and the ultimate moment ($M_u$) of FRP–FLWC beams:

1. Strain in the concrete and the FRP reinforcement is proportional to the distance from the neutral axis;
2. The tensile behavior of the FRP reinforcement is linearly elastic;
3. The stress-strain relationships of the FLWC under uniaxial tension and compression are assumed according to ACI 544.4R [18] and JGJ12 [19], respectively;
4. The reinforcing steel rebar in the compression zone is yielded;
5. A perfect bond exists between concrete and FRP reinforcement.
where $A'$ is the area of compressive reinforcement; $b$ is the beam width; $d$ is the beam effective depth; $f_c$ is the prism compressive strength of concrete; $f_f$ is the tensile strength of the FRP bars; $f_{1-F}$ is the tensile strength of the fiber-reinforced concrete; $f_y$ is the yield strength of the steel rebars; $\varepsilon_{ct}$ is the peak tensile strain of the concrete; $\varepsilon_{cu}$ is the ultimate compressive strain of the concrete which assumed to be 0.0033 according to GB 50608 [20]; $\gamma_1$ is the coefficient of neutral axis depth; $\gamma_2$ is the coefficient of effective tensile concrete depth; $\alpha_1$, $\beta_1$ are the stress-block factors for concrete, which can be determined by Equation (2), respectively.

$$\begin{align*}
\alpha_1 &= 1 - 0.002(f_{cu} - 40) \\
\beta_1 &= 0.75 - 0.001(f_{cu} - 40)
\end{align*}$$

where $f_{cu}$ is the cube compressive strength of concrete.

Combining Equations (1) and (2), the unknown value $\gamma_1$ and $\gamma_2$ can be obtained. Thereafter, the $\rho_{fb}$ and the $M_u$ can be expressed by Equations (3) and (4), respectively.

$$\rho_{fb} = \frac{1}{f_{fu}} \left( \alpha_1 \beta_1 \gamma_1 f_c b d + A' f'_y \frac{f_f}{bd} - \frac{\gamma_2 f_{1-F} bd^2}{2} \right)$$

$$M_u = \alpha_1 \beta_1 \gamma_1 f_c b d^2 \left( 1 - \frac{\gamma_1}{2} \right) + A' f'_y (d - a'_s) - \frac{\gamma_2 f_{1-F} bd^2}{2} \left( 1 - \gamma_1 - \frac{2 \gamma_2}{3} \right)$$

where $a'_s$ is the concrete cover measured from the centroid of compressive reinforcement to the extreme compressive surface.

### 2.3. Prediction for Concrete Crushing Failure Mode

For beams that are damaged due to concrete crushing, based on the strain and stress conditions displayed in Figure 2, strain compatibility and force equilibrium are considered as follows:

$$\begin{align*}
\frac{\varepsilon_{cu}}{\gamma_1 d} &= \frac{\varepsilon_{ct}}{\gamma_2 d} = \frac{\varepsilon_f}{(1 - \gamma_1)d}
\end{align*}$$

![Figure 1. Strain and stress conditions for balanced failure mode.](image-url)
where $f_f$ is the tensile stress of the FRP bars; $\varepsilon_f$ is the tensile strain of the FRP bars; $\rho_f$ is the reinforcement ratio of the FRP bars.

![Figure 2](image1.png)

Figure 2. Strain and stress conditions for concrete crushing failure mode.

As for the ultimate moment, Equation (4) can be also employed in the concrete crushing case since similar simplification of the stress distribution of concrete in the tension and compression zone is adopted.

3. Deflection Model of FRP-Reinforced Beams

3.1. Prediction for Beams without Fibers

The curvature of FRP-RC members can be calculated based on the $\varepsilon_f$, considering its nonuniform distribution between cracks, as shown in Figure 3.

$$
\frac{1}{\rho} = \frac{\varepsilon_f + \varepsilon_c}{d} = \frac{\psi \varepsilon_f + \varepsilon_c}{d}
$$

(6)

where $\varepsilon_c$ is the compressive strain of the concrete; $\varepsilon_c$ is the average compressive strain of the concrete; $\varepsilon_f$ is the average tensile strain of the FRP bars; $\psi$ is the nonuniformity coefficient of strain.

![Figure 3](image2.png)

Figure 3. Calculation of curvature based on the fiber-reinforced polymer (FRP) tensile strain.
In GB 50608, the semi-empirical equation of the short-term stiffness ($B_s$) was established by solving first the curvature (Equation (7)), based on the stiffness analytic method shown in Figure 3.

$$B_s = \frac{E_f A_f d^2}{\psi + 0.2 + 6\alpha_f\rho_f}$$

(7)

where $A_f$ is the area of tension FRP bars; $\alpha_f$ is the ratio of modulus of elasticity of FRP bars to modulus of elasticity of concrete; $E_f$ is the modulus of elasticity of the FRP bars; $\eta$ is the coefficient of the internal lever arm length, which is 0.87 and 0.85 for normal weight concrete and LWC beams, respectively. The $\psi$ was given as

$$\psi = 1.1 - 0.65 \eta A_f f_t d M \rho_{te}$$

(8)

where $f_t$ is the tensile strength of concrete; $M$ is the actual bending moment; $\rho_{te}$ is the reinforcement ratio of the FRP bars on the basis of the effective cross-sectional area of concrete. It should be mentioned that the empirical parameters employed in Equations (7) and (8) were the same as those for steel reinforced beams.

Since the parameter $\psi$ was included to reflect the variation in strain along the longitudinal reinforcement, accounting for the distinctive material properties of FRP reinforcements as compared with steel rebars, the $\psi$ in Equation (8) might not be applicable to beams reinforced with FRP bars. Through regression analysis on experimental deflections of GFRP-reinforced flexural members at service-load levels, the empirical formula of the nonuniformity coefficient of strain in FRP bars ($\psi_f$) was presented in the following Equation [21]:

$$\psi_f = 1.3 - 0.74 \eta A_f f_t d M \rho_{te}$$

(9)

By substituting Equation (9) into Equation (7), the short-term stiffness of beams reinforced with FRP bars ($B_{s,f}$) can be expressed by

$$B_{s,f} = \frac{E_f A_f d^2}{\frac{1.3}{\eta} - 0.74 A_f f_t d M \rho_{te} + 0.2 + 6\alpha_f\rho_f}$$

(10)

3.2. Prediction for Beams Reinforced with Fibers

It has been proven that the concrete tensile strength increases with the volume fraction ($\rho_{fi}$) and aspect ratio ($l_{fi}/d_{fi}$) of the fibers [22]. Based on this, the conversion between the tensile strengths of the concrete with and without fibers can be performed according to Equation (11).

$$f_{t-F} = f_t \left(1 + \alpha_t \lambda_{fi}\right)$$

(11)

where $\alpha_t$ is the influence coefficient of fiber on the tensile strength of the concrete; $\lambda_{fi}$ is the feature parameter of fiber, which can be calculated by

$$\lambda_{fi} = \frac{\rho_{fi} l_{fi}}{d_{fi}}$$

(12)

where $l_{fi}$ and $d_{fi}$ are the length and the diameter of fiber, respectively.

However, in the case of FRP-RC beams, it was observed that the improvement of their stiffness from the bridging effect of the fibers was reduced with the increasing reinforcement ratio [23]. With this
in mind, the form of the amplification factor \((1 + \alpha_i \lambda_f)\) in Equation (11) is modified and the stiffness of FRP–FLWC beams \((B_{s,f-F})\) can be expressed as

\[
B_{s,f-F} = \left(1 + \alpha_i \lambda_{F_i} \frac{\rho_{fb}}{\rho_f}\right) B_{s,f} \tag{13}
\]

Based on the tensile tests on the plain and fibrous LWC, the \(\alpha_i\) can be determined by Equation (14), which is derived from Equation (11).

\[
\alpha_i = \frac{f_{i-F} - f_{i}}{\lambda_{F_i} f_{i}} \tag{14}
\]

3.3. Verification Based on Fiber-Reinforced Normal Weight Concrete (FNWC) Beams

In order to evaluate the accuracy of the short-term stiffness model proposed, the measured and predicted deflections under service load levels \((M_s)\) of FNWC beams reinforced with FRP bars tested in the literature are compared in Table 1 and Figure 4. It should be mentioned that the tensile strength of the concrete was ignored in the calculation of \(\rho_f\) due to its absence in most literature. Furthermore, since the ratio between the cracking moment of the beams was considered close to that between the tensile strength of the concrete used [23], the factor \((f_{i-F} - f_{i})/f_{i}\) in Equation (14) was replaced by \((M_{cr-F} - M_{cr})/M_{cr}\), where \(M_{cr-F}\) and \(M_{cr}\) are the cracking moments of the FRP-reinforced beams with and without fibers, respectively.

![Figure 4](image-url)

**Figure 4.** Ratios of experimental-to-predicted deflections for fiber-reinforced normal weight concrete (FNWC) beams.

The results in Figure 4 indicated that the estimations were generally in good agreement with the experimental results, although the definition of the service load given by the researchers was not unified. However, specimens with higher \(\rho_f/\rho_{fb}\) tended to yield higher experimental-to-predicted deflection ratios \((\Delta_{Exp}/\Delta_{Pred})\). It can be derived that the influence of \(\rho_f/\rho_{fb}\) on the \(B_{s,f-F}\) presented in Equation (13) was overestimated.
Table 1. Comparisons between the theoretical and experimental deflections of FNWC beams at \(M_s\).

| Reference                  | Spec. | Service Load | Type of Bar | Type of Fiber | \(L\) (mm) | \(h\) (mm) | \(b\) (mm) | \(f'_c\) (MPa) | \(f_{fu}\) (MPa) | \(E_f\) (GPa) | \(\rho_f\) (%) | \(\rho_f/\rho_{fb}\) | \(\Delta_{Exp}\) (mm) | \(\Delta_{Exp}/\Delta_{Pred}\) |

4. Models Recommended by Design Codes

4.1. Balanced Reinforcement Ratio and Ultimate Moment

Strain compatibility approaches were used to calculate $\rho_{fb}$ and $M_u$ in current design codes. The $\rho_{fb}$ was determined from Equation (15) for ACI 440.1R and CSA S806, and Equation (16) for GB 50608, respectively. Moreover, stress-block factors for concrete ($\alpha_1$, $\beta_1$) were computed by Equation (2), Equation (17) and Equation (18) for GB 50608, ACI 440.1R and CSA S806, respectively.

$$\rho_{fb} = \frac{\alpha_1 f_{fc} f_{fu}}{f_{fu} E_{fc} \varepsilon_{cu} + f_{fu}}$$  \hspace{1cm} (15)

$$\rho_{fb} = \frac{\alpha_1 f_{fc} \beta_1 \varepsilon_{cu}}{f_{fu} \varepsilon_{cu} + f_{fu} / E_f}$$  \hspace{1cm} (16)

$$\begin{align*}
\alpha_1 &= 0.85 \\
\beta_1 &= 0.85 - \frac{0.05(f'_c - 28)}{7} \geq 0.65 \\
\end{align*}$$  \hspace{1cm} (17)

$$\begin{align*}
\alpha_1 &= 0.85 - 0.0015f'_c \geq 0.67 \\
\beta_1 &= 0.97 - 0.0025f'_c \geq 0.67 \\
\end{align*}$$  \hspace{1cm} (18)

In ACI 440.1R, the $M_u$ is given by Equation (19) when $\rho_f \geq \rho_{fb}$

$$M_u = \rho_{ff} \left( 1 - 0.59 \frac{\rho_{ff} f_{fc}}{f'_c} \right) b d^2$$  \hspace{1cm} (19)

where the tensile strength of FRP bars ($f_f$) could be calculated using the following equation:

$$f_f = \left[ \frac{\left( \frac{E_f \varepsilon_{cu}}{4} \right)^2 + 0.85 \beta_1 f'_c \rho_f E_f \varepsilon_{cu} - 0.5 E_f \varepsilon_{cu}}{\rho_f E_f \varepsilon_{cu}} \right] \leq f_{fu}$$  \hspace{1cm} (20)

In ISIS M03 [26], the $M_u$ for beams with $\rho_f \geq \rho_{fb}$ could be obtained according to Equation (21).

$$M_u = \alpha_1 \beta_1 f'_c b c \left( d - \frac{\beta_1 c}{2} \right)$$  \hspace{1cm} (21)

where $c$ is the neutral axis depth from the top compression fiber, which was determined using Equation (22) as follows:

$$c = \frac{0.5 A_f E_f \varepsilon_{cu}}{\alpha_1 \beta_1 f'_c b} \left[ \sqrt{1 + \frac{4 \alpha_1 \beta_1 f'_c}{\rho_f E_f \varepsilon_{cu}}} - 1 \right]$$  \hspace{1cm} (22)

Based on semiempirical considerations, GB 50608 recommended $M_u$ equation as:

$$M_u \leq f_{ff} A_f \left( d - \frac{f_{ff} A_f}{2 f'_c b} \right)$$  \hspace{1cm} (23)

The experienced formula of $f_f$ was expressed as a piecewise function:

$$f_f = \begin{cases} 
    f_{fu} \left[ 1 - 0.211 \left( \frac{\rho_f}{\rho_{fb}} - 1 \right) \right]^{0.2} & \text{for } \rho_{fb} < \rho_f < 1.5 \rho_{fb} \\
    f_{fu} \left( \frac{\rho_f}{\rho_{fb}} \right)^{-0.50} & \text{for } 1.5 \rho_{fb} \leq \rho_f 
\end{cases}$$  \hspace{1cm} (24)
4.2. Deflection

In design codes GB 50608, ISIS-M03 and ACI 440.1R, the procedures to calculate the deflections of simply supported FRP-RC beams under four-point bending entailed the calculation of the average stiffness throughout the beam length.

\[ \Delta = \frac{Pa}{48A} \left(3L^2 - 4a^2\right) \]  \hspace{1cm} (25)

where \( a \) is the beam shear span; \( P \) is the applied concentrated load; \( \Delta \) is the midspan deflection; \( A \) represents the beam average stiffness, which is \( B_s \) in GB 50608, and is the product of the elastic modulus of the concrete \( (E_c) \) and the effective moment of inertia \( (I_e) \) in ISIS-M03 and ACI 440.1R.

ACI 440.1R employed the \( I_e \) in predicting the deflection of FRP-RC beams. The formula for \( I_e \) was modified Bischoff’s expression [27,28]:

\[ I_e = \frac{I_{cr}}{\left(1 - \gamma \left(\frac{M_{cr}}{M_a}\right)^2\right) \left[1 - \frac{I_{cr}}{I_g}\right]} \]  \hspace{1cm} (26)

where \( I_{cr} \) is the cracked moment of inertia; \( I_g \) is the gross moment of inertia; \( M_a \) is the actual bending moment; The reduction factor \( \gamma \) was included to account for the variation in stiffness along the length of the member

\[ \gamma = 1.72 - 0.72 \left(\frac{M_{cr}}{M_a}\right) \]  \hspace{1cm} (27)

The alternative expression for \( I_e \) suggested by ISIS-M03 was confirmed to be conservative over the entire range of the test specimens by Mota et al. [29]:

\[ I_e = \frac{l_I I_{cr}}{l_I + \left(1 - 0.5 \left(\frac{M_{cr}}{M_a}\right)^2\right) (l_I - I_{cr})} \]  \hspace{1cm} (28)

where \( l_I \) is the second moment of area of the uncracked section transformed to concrete.

CSA S806 predicted the deflection of FRP-RC members using moment–curvature method:

\[ \Delta = \frac{PL^3}{24E_c I_{cr}} \left[3 \left(\frac{a}{L}\right) - 4 \left(\frac{a}{L}\right)^2 - 8 \left(1 - \frac{I_{cr}}{I_g}\right) \left(\frac{L_{u}}{L}\right)^3\right] \]  \hspace{1cm} (29)

where \( L_u \) is the uncracked beam length.

5. Experimental Study of GFRP-Reinforced LWC Beams

5.1. Test Specimens and Material Properties

To study the influence of steel fibers and FRP reinforcement ratio, six GFRP-reinforced LWC beams were constructed and tested under four-point bending. Beam geometry and the loading and support arrangement are illustrated in Figures 5 and 6, respectively. Strain gauges were installed on the FRP reinforcement at midspan and on the top surface of the concrete in the constant moment region to monitor their strain during the loading process.
The diameters and mechanical properties of the GFRP bars were determined according to ACI 440.3R [30]. Steel rebars with diameter, tensile strength and elastic modulus of 10.62 mm, 445 MPa and 204 GPa, respectively, were used as transverse and top reinforcements. Table 3 presents the mechanical properties of the GFRP bars and the details of the tested specimens.

Table 2. Properties of steel fiber.

| Type      | \( l_f \) (mm) | \( d_f \) (μm) | Density (kg·m\(^{-3}\)) | Tensile Strength (MPa) | Shape     | Surface  |
|-----------|----------------|----------------|--------------------------|------------------------|-----------|----------|
| Steel fiber | 13             | 200            | 7800                     | >3000                  | Straight  | Smooth   |

Sand coated GFRP bars with a diameter of 13.77 mm were used as longitudinal reinforcements. The diameters and mechanical properties of the GFRP bars were determined according to ACI 440.3R [30]. Steel rebars with diameter, tensile strength and elastic modulus of 10.62 mm, 445 MPa and 204 GPa, respectively, were used as transverse and top reinforcements. Table 3 presents the mechanical properties of the GFRP bars and the details of the tested specimens.

LWC with steel fiber contents of 0% and 0.6%, respectively, were used to fabricate the specimens. The properties of steel fibers are listed in Table 2. The cube compressive strength \( f_{cu} \) were obtained from testing three 100 mm cubes for each beam on the day of testing. The tensile strengths of the LWC and steel fiber-reinforced lightweight aggregate concrete (SFLWC) were 5.12 MPa and 8.16 MPa, respectively.

Table 3. Summary of specimen details and test results.

| Specimen Type | Type | Ie (kN·m) | \( f_{cu} \) (MPa) | \( f_{t} \) (MPa) | \( \rho \) (μm) | \( \mu \) (μm) | \( c_c \) (kN) |

\( \Delta \) is the displacement at 0.3\( M_u \) and \( 0.5 M_u \).

The beams were labeled as following: LC or SL for lightweight aggregate concrete or steel fiber-reinforced lightweight aggregate concrete; then G for GFRP bars; finally, the reinforcement ratio (percent). For instance, LCG–0.92 indicates a lightweight aggregate concrete beam with GFRP reinforcement ratio of 0.92%.

5.2. Test Results

The test results are shown in Table 3, and the typical failure shapes of the specimens are depicted in Figure 7. Crushing of lightweight aggregates (LWAs) could be observed at the fractured surface in the compression zone (Figure 7b–d), owing to their low compressive strength. This was a distinctive fracture pattern of LWC beams as compared with the ordinary concrete ones. Figure 8 shows the strains in the tensile FRP bars and the compressive concrete against the applied moment of the specimens. The reinforcement strain of beam SLC–0.92 is not presented since the strain gauges were broken down. Both the moment–FRP and concrete strain responses could be divided into two segments. The first stage was a steep linear curve corresponding to the behavior before cracking, wherein the FRP bars and concrete exhibited little strain, while the second was a basically linear segment represented the post-cracking behavior. In addition, increasing the reinforcement ratio and adding steel fibers could restrain the deformation of the FRP bars, indicating their benefit achieved in flexural stiffness of the beams. Figure 8 also illustrates that the concrete strain at the maximum load level generally exceeded the assumed concrete compressive strain recommended by GB 50608.

Figure 7. Typical failure shapes: (a) SLG–0.92; (b) LCG–0.92; (c) SLG–1.64; (d) SLG–2.66 (dimensions in millimeters).

Figure 8 also illustrates that the concrete strain at the maximum load level generally exceeded the assumed concrete compressive strain recommended by GB 50608.

6. Comparison between the Experimental and Predicted Results

6.1. Balanced Reinforcement Ratio and Ultimate Moment of LWC Beams

The relative reinforcement ratio \( \rho_f/\rho_{fb} \) of the tested specimens according to GB 50608, CSA S806, ACI 440.1R and Equation (3) are presented in Table 4. It is to be noted that the tensile strength of the LWC without steel fibers was ignored. The results indicated that specimens with \( \rho_f/\rho_{fb} \) close to 1 all possibly damaged by balanced failure, which could be attributed to the discreteness of material strength. In addition, the greater \( \rho_f/\rho_{fb} \) lent a higher degree of concrete crushing when FRP bars ruptured (Figure 7a–c). As presented in Table 4, CSA S806 provided more conservative \( \rho_f/\rho_{fb} \) than ACI 440.1R although the same \( \rho_{fb} \) equation was used. This could be ascribed to the higher concrete compressive strain assumed. Additionally, the proposed model provided the lowest \( \rho_f/\rho_{fb} \) among all the models since the contribution of the compressive reinforcements was included.

| Spec. | \( \rho_f/\rho_{fb} \) | \( M_{u,Exp}/M_{u,Pred} \) |
|-------|------------------|----------------------------|
|       | ACI 440.1R | CSA S806 | GB 50608 | Proposed Model | ACI 440.1R | CSA S806 | GB 50608 | Proposed Model |
| LCG–0.92 | 1.09 | 0.89 | 0.98 | 0.76 | 1.09 | 1.05 | 0.98 | 1.09 |
| SLG–0.92 | 0.83 | 0.66 | 0.71 | 0.59 | 1.22 | 1.19 | 1.18 | 1.01 |
| LCG–1.64 | 1.78 | 1.39 | 1.52 | 1.20 | 1.24 | 1.11 | 1.11 | 1.05 |
| SLG–1.64 | 1.46 | 1.17 | 1.26 | 1.04 | 1.31 | 1.19 | 1.20 | 0.89 |
| LCG–2.66 | 2.94 | 2.33 | 2.55 | 1.99 | 1.27 | 1.15 | 1.09 | 1.08 |
| SLG–2.66 | 2.46 | 1.96 | 2.11 | 1.72 | 1.39 | 1.26 | 1.20 | 1.15 |
| Average | 1.25 | 1.16 | 1.13 | 1.02 | 1.25 | 1.16 | 1.13 | 1.02 |

Based on the actual failure mode, the experimental-to-predicted ultimate capacity ratios \( (M_{u,Exp}/M_{u,Prod}) \) of the specimens according to design codes and the proposed model are summarized in Table 4. Unfilled and filled points are used to represent the \( M_{u,Exp}/M_{u,Prod} \) of the LWC and SFLWC specimens in Figure 9, respectively. As shown in Figure 9, the estimated \( M_u \) according to the design codes were generally lower than the experimental results since the contribution of the steel fibers and the reinforcement in the compression zone was ignored.
The proposed model were in good agreement with the experimental results with an average predicted deflections based on the design codes, owing to the benefits offered by the steel fibers. At 2019± and 1.07

440.1R and the proposed model showed accurate predictions with average

CSA S806 and ISIS-M03 overestimated the estimated by design codes ACI 440.1R, CSA S806 and GB 50608 and the proposed model.

In the case of the SFLWC specimens, GB 50608, CSA S806, and ACI 440.1R provided conservative ultimate capacities with average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 1.19 ± 0.01, 1.21 ± 0.04, 1.31 ± 0.09, respectively. On the other hand, the proposed model yielded most accurate predictions with an average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 1.02 ± 0.13.

As a perfect bond between concrete and FRP reinforcement was assumed, the deformation caused by relative slip between the LWC and the FRP reinforcement was ignored. Based on the plane section assumption, the actual depth of the compression zone was lower than the calculated value. Therefore, this assumption would result in overestimation of the ultimate capacity.

6.2. Deflection of LWC Beams

Bischoff et al. [31] recommended a load corresponding to 30% of the

M

s

as service load (M

s

) for FRP-RC beams. Table 5 and Figure 10 compare the experimental deflections with the theoretical results estimated by design codes ACI 440.1R, CSA S806, ISIS-M03 and GB 50608 and the proposed model. The

M

/ ∆

u,Exp

/ ∆

u,Pred

of the LWC and SFLWC specimens with varied

ρf

are represented by unfilled and filled points in Figure 10, respectively. For LWC beams, CSA S806 and ISIS-M03 overestimated the deflections with average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 0.83 ± 0.06 and 0.86 ± 0.04, respectively. On the other hand, GB 50608 gave unconservative predictions with an average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 1.34 ± 0.20. Moreover, ACI 440.1R and the proposed model showed accurate predictions with average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 1.01 ± 0.06 and 1.07 ± 0.13, respectively.

In the case of the SFLWC specimens, the measured results were generally lower compared to the predicted deflections based on the design codes, owing to the benefits offered by the steel fibers. At

M

L, CSA S806 and ISIS-M03 provided significantly conservative estimations with average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 0.56 ± 0.20 and 0.59 ± 0.20, respectively. ACI 440.1R and GB 50608 slightly overestimated the deflections with average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 0.73 ± 0.17 and 0.88 ± 0.08, respectively. Furthermore, it was confirmed that the deflections could be reasonably estimated by the proposed model with an average

M

/ ∆

u,Exp

/ ∆

u,Pred

of 1.06 ± 0.04. Similarly, the results in Figure 10 could be taken as an evidence for the overestimation of the influence of

ρf

/ ∆

ρfb

in Equation (12). Considering the overall predictions of LWC and SFLWC beams, the proposed model provided the lowest COV among the equations used, namely, 7%.

Figure 9. Ratios of experimental-to-predicted ultimate capacity.

For LWC beams, the average

M

of 1.19 ± 0.01, 1.21 ± 0.04, 1.31 ± 0.09, respectively. For LWC beams, CSA S806 and ISIS-M03 overestimated the estimated by design codes ACI 440.1R, CSA S806, and GB 50608 and the proposed model.
Table 5. Experimental-and-predicted deflections ratios for LWC beams.

| Spec.   | ACI 440.1R | CSA S806 | GB 50608 | ISIS-M03 | Proposed Model |
|---------|------------|----------|----------|-----------|----------------|
| LCG–0.92 | 1.07       | 0.76     | 1.54     | 0.89      | 1.19           |
| SLG–0.92 | 0.58       | 0.36     | 0.81     | 0.59      | 1.10           |
| LCG–1.64 | 1.01       | 0.86     | 1.35     | 0.88      | 1.10           |
| SLG–1.64 | 0.71       | 0.56     | 0.85     | 0.79      | 1.03           |
| LCG–2.66 | 0.96       | 0.86     | 1.14     | 0.81      | 0.94           |
| SLG–2.66 | 0.91       | 0.75     | 0.97     | 0.40      | 1.05           |
| Average  | 0.87       | 0.69     | 1.11     | 0.79      | 1.07           |
| COV (%)  | 22         | 28       | 26       | 24        | 7              |

Figure 11 compares the experimental and theoretical moment–deflection responses of the tested specimens. As the figure shows, for the LWC beams, the proposed equation yielded similar load versus midspan deflection behaviors with the test data during the entire loading period. However, for beams reinforced with steel fibers, the proposed model yielded accurate estimations only at service-load levels. This could be attributed to the fact that the improvement of the stiffness from the steel fibers gradually diminished as the fibers pulled out in succession at high-load levels.
7. Conclusions

This paper establishes the balanced reinforcement ratio, ultimate moment and deflection equations of LWC beams with and without fibers. The accuracy of the proposed models was investigated based on experimental results. The following conclusions can be drawn:

(1) Increasing the reinforcement ratio and adding steel fibers were shown to be effective in decreasing the FRP strain of FRP-reinforced LWC beams.

(2) Design codes ACI 440.1R, ISIS-M03, GB 50608, and CSA S806 generally underestimated the flexural capacity of the GFRP-LWC beams with and without steel fibers. The predictions obtained from the proposed ultimate moment equation were in good agreement with the experimental results.

(3) For GFRP-SFLWC beams, the design codes showed conservative deflection values at $M_s$, while the proposed short-term stiffness model provided reasonable predictions with low dispersion degree.

(4) In both case of SFLWC and FNWC beams, specimens with higher $\rho_f/\rho_{fb}$ tended to yield higher experimental-to-predicted deflection ratios based on the proposed model. Further research will be conducted involving rational consideration of the FRP reinforcement amount in the deflection model of fiber-reinforced beams.
