**Abstract**

In eukaryotes, type 1A topoisomerases (topos) act with RecQ-like helicases to maintain the stability of the genome. Despite having been the first type 1A enzymes to be discovered, much less is known about the involvement of the *E. coli* topo I (*topA*) and III (*topB*) enzymes in genome maintenance. These enzymes are thought to have distinct cellular functions: topo I regulates supercoiling and R-loop formation, and topo III is involved in chromosome segregation. To better characterize their roles in genome maintenance, we have used genetic approaches including suppressor screens, combined with microscopy for the examination of cell morphology and nucleoid shape. We show that topoA mutants can suffer from growth-inhibitory and supercoiling-dependent chromosome segregation defects. These problems are corrected by deleting *recA* or *recQ* but not by deleting *recI* or *recO*, indicating that the RecF pathway is not involved. Rather, our data suggest that RecQ acts with a type 1A topo on RecA-generated recombination intermediates because: 1-topo III overproduction corrects the defects and 2-*recQ* deletion and topo III *overproduction* are epistatic to *recA* deletion. The segregation defects are also linked to over-replication, as they are significantly alleviated by an *oriC::aph* suppressor mutation which is *oriC*-competent in *topA* null but not in isogenic *topA*+ cells. When both topo I and topo III are missing, excess supercoiling triggers growth inhibition that correlates with the formation of extremely long filaments fully packed with unsegregated and diffuse DNA. These phenotypes are likely related to replication from R-loops as they are corrected by overproducing RNase HI or by genetic suppressors of double *topA mnaH* mutants affecting constitutive stable DNA replication, *dtnA::aph* and *rne::aph*, which initiate from R-loops. Thus, bacterial type 1A topos maintain the stability of the genome (i) by preventing over-replication originating from *oriC* (topo I alone) and R-loops and (ii) by acting with RecQ.

Introduction

Type 1A topoisomerases (topos) are essential and ubiquitous enzymes found in bacteria, archaea and eukarya [1,2]. They all require single-stranded DNA (ssDNA) regions for activity. Such substrates can already be present, for example, in negatively supercoiled DNA, at the replication fork and in R-loops, or can be generated by the action of proteins, such as helicases or RNA polymerases. *E. coli* topo I, the first topo to be discovered [3], is the prototype enzyme of this family. This enzyme binds to ssDNA close to double-stranded DNA (dsDNA) regions [4] and is therefore well suited to relax the excess negative supercoiling generated behind RNA polymerase molecules during transcription [5], or introduced by DNA gyrase, the enzyme that negatively supercoils DNA in bacteria [6].

The best evidence for a major role of topo I in the regulation of supercoiling came from the observation that *topA* null mutants accumulate compensatory mutations in *gyrA* or *gyrB* genes allowing them to grow [7]. These mutations decrease the supercoiling activity of gyrase which leads to a reduction in the global chromosome supercoiling level below that of wild-type cells [8]. The role of topo I in transcription is supported by the finding that it physically interacts with RNA polymerase [9]. One major consequence of excess negative supercoiling is R-loop formation [10]. This is supported by the observation that the growth defect of *topA* null mutant can be partially compensated by RNase HI overproduction [11]. Evidence for extensive R-loop formation in the absence of topo I has been provided both *in vitro* and *in vivo* [12–15]. It is believed that topo I prevents R-loop formation mainly by relaxing transcription-induced negative supercoiling [15].

After a temperature downshift to reactivate gyrase in a *topA* null mutant carrying a *gyrB(Ts)* allele, RNase HI overproduction was shown to prevent a transient growth arrest that correlated with the accumulation of excess negative supercoiling (hyperm negative supercoiling) and extensive RNA degradation [16]. RNase HI overproduction was found both to reduce the accumulation of excess negative supercoils and to promote their rapid removal by topo IV [16,17], the other enzyme that can relax negative supercoiling in *E. coli* [18]. Moreover, evidence for R-loops impeding transcription of ribosomal RNA genes (*rrn* operons) in *topA* null mutants has been reported [19]. Interestingly, R-loop-dependent gene expression inhibition related to RNA polymerase arrest and RNA degradation has also been reported for yeast cells lacking topo I, a type 1B topo [20]. Thus, R-loop-mediated impairment of gene expression appears to be a major mechanism by which excess negative supercoiling inhibits growth.

*E. coli* topo I is a relatively abundant protein being in the top 25% of the most abundant proteins in *E. coli* (134 ppm) [21]. The
Author Summary

DNA topoisomerase III is a ubiquitous enzyme that plays a role in the topological problems associated with replication, transcription, and recombination. Eukaryotic enzymes of the type 1A family work with RecQ-like helicases such as BLM and Sgs1 and are involved in genome maintenance. Interestingly, *E. coli* topo I, a type 1A enzyme and the first topoisomerase to be discovered, appears to have distinct cellular functions that are related to supercoiling regulation and to the inhibition of R-loop formation. Here we present data strongly suggesting that these cellular functions are required to inhibit inappropriate replication originating from either oriC, the normal origin of replication, or R-loops that can otherwise lead to severe chromosome segregation defects. Avoiding such inappropriate replication appears to be a key cellular function for genome maintenance, since the other *E. coli* type 1A topo, topo III, is also involved. Furthermore, our data suggest that bacterial type 1A topos, like their eukaryotic counterparts, can act with RecQ in genome maintenance. Altogether, our data provide new insight into the role of type 1A topos in genome maintenance and reveal an interplay between these enzymes and R-loops, structures that can also significantly affect the stability of the genome as recently shown in numerous studies.

Similar to eukaryotic type 1A topos (see below), topo III activity was shown to be stimulated by RecQ helicase in vitro [35–37], but these two proteins do not physically interact. Evidence for RecQ acting with topo III in *E. coli* cells has been reported [30]. However, because some important properties of the strains used in this work could not be observed in an independent study, the conclusion that RecQ acts with topo III has been questioned [38].

Saccharomyces cerevisiae type 1A topo was the first enzyme of this family to be discovered in eukaryotic cells [39]. Being the third topo identified in this organism, it was named Top3. The existence of this topo was revealed following the isolation of a mutation, in *top3*, that stimulated recombination between repeated sequences [38]. Interestingly, phenotypes of *top3* mutants including slow growth and sporulation deficiency were suppressed to different extents by inactivating *SGS1*, encoding the RecQ homolog of *S. cerevisiae*, or by overproducing *E. coli* topo I [38–40]. Moreover, deleting *RAD51*, encoding the RecA homolog of *S. cerevisiae*, was shown to rescue the slow growth phenotype of *top3* mutants [41]. Altogether, these data suggested that Sgs1 processed recombination intermediates to generate structures that could only be resolved by a type 1A topo, such as *Top3* or *E. coli* topo I.

Physical interactions between type 1A topos (named topo III in higher eukaryotes) and their RecQ-like partner from eukaryotic organisms (e.g. BLM in humans and in *Drosophila*) have been demonstrated [1, 39, 42, 43]. It is now well established that these complexes can efficiently resolve homologous recombination intermediates (Double Holliday Junctions; DHJs) without genetic exchange [1, 44–46]. Reactions of BLM with topo III are often stimulated by the presence of RPA, the SSB homolog of eukaryotes that presumably stabilizes the BLM-generated ssDNA region, the substrate for topo III [44, 46]. Eukaryotic topo III enzymes have a higher requirement for ssDNA than *E. coli* topo I and, in fact, they are generally considered to be more closely related to *E. coli* topo III than topo I [1].

In *E. coli*, an interplay between topo I and III has been reported in two instances. In the first one, the *topB* gene was isolated as a multicopy suppressor of a *topA* null mutant [47]. Despite the significant correction of the growth defect of the *topA* null mutant by overproducing topo III, relaxation of the excess negative supercoiling introduced by gyrase was barely detected. This is consistent with our observation that topo III overproduction, unlike RNase HI overproduction, is unable to prevent the supercoiling-dependent transient growth arrest of a *topA gyrB(Ts)* strain, following a temperature downshift [16]; Baakhini and Drolet, unpublished). These results might have suggested that topo III overproduction complemented a yet unknown function of topo I that was not directly related to excess supercoiling. Indeed, here we present genetic evidence for an important role of topo I acting with RecQ to resolve RecA-dependent recombination intermediates that otherwise inhibit chromosome segregation. Moreover, our data suggest that the requirement for this activity is related to over-replication mostly from oriC that takes place in the absence of *topA*, presumably due to excess negative supercoiling.

In the second instance, deleting *topB* from a *topA* null mutant carrying a *gyrA* or *gyrB* compensatory mutation, led to the formation of very long filaments with unsegregated nucleoids having abnormal structures and, eventually, to growth arrest [48]. Here, our data suggest that these phenotypes are exacerbated by excess negative supercoiling and are mostly related to over-replication from R-loops.

Overall, our data demonstrate that bacterial type 1A topos maintain the stability of the genome by preventing unregulated replication and at least one of its consequences, namely the inhibition of chromosome segregation.

*topA* gene is under the control of promoters recognized by different sigma factors, σ52, σ5 and σ70 and its expression is important for *E. coli*’s response to various stresses including heat and oxidative shock [22]. RNase HI overproduction was shown to partially restore the expression of σ52-regulated genes required for the heat shock response [23].

Although studies of topo I mostly focused on its role in supercoiling regulation and its effect on gene expression, evidence for the involvement of this enzyme in other DNA transactions such as chromosome segregation and replication initiation has been provided [17, 24–27]. Interestingly, one of the first functions to be proposed for topo I was a role as a specificity factor to inhibit replication initiation outside *oriC*, such as initiation from R-loops, that could occur in an *in vitro* reconstituted system for *oriC*-dependent replication [28]. However, there is no experimental evidence for such a role of topo I *in vivo*.

*E. coli* topo III, the second type 1A topo to be discovered, has a much higher preference for ssDNA than *E. coli* topo I [29]. As a consequence, topo III is very inefficient in relaxing DNA with a physiological supercoiling density and, in fact, this enzyme plays no role in supercoiling regulation [18, 30]. However, topo III was shown to be a very potent decatenase during replication *in vitro* provided that a ssDNA region was present on the DNA substrate for the binding of the enzyme [29]. The presence of a unique amino-acid sequence in the topo III protein named the “decatenation loop” (absent in eukaryotic type 1A enzymes), was found to be essential for the decatenation of replication intermediates [31].

Unlike topo I, topo III is a protein of low abundance (9.4 ppm) [21]. Moreover, as opposed to *topA* null mutants, cells lacking topo III activity display no growth defects [32]. Recently, it has been shown that topo III plays a role in chromosome segregation *in vivo* that is likely related to replication, as this function was shown to be mostly required when the activity of topo IV [33], the main cellular decatenase, or gyrase [34] was severely impaired. Topo III physically interacts with SSB protein and this interaction presumably allows topo III to act at the replication fork in the cell [35].
Results

Supercoiling-dependent growth and chromosome segregation defects in cells lacking topo I activity

To look for chromosome segregation defects in a topA null mutant, cells of a ΔtopA gyrB(Ts) strain were stained with DAPI and prepared for microscopy such that both cell morphology and DNA content could be examined. By growing the cells at 30°C, the permissive temperature for gyrase, we could test the true effect of losing topo I on nucleoid shape. As can be seen in Figure 1A, whereas nucleoids of gyrB(Ts) cells were well separated and compact, those of isogenic gyrB(Ts) ΔtopA cells were less compact and clearly not separated, thus showing chromosome segregation defects.

To verify if these problems were related to excess negative supercoiling, topA null cells were grown at 37°C so that gyrase activity was reduced. At this temperature the chromosome supercoiling level decreases below that of wild-type cells and, as a result, topA null cells can grow robustly [11,49]. At 37°C, chromosome segregation in the gyrB(Ts) ΔtopA strain was significantly improved, as many cells had well separated and more compact nucleoids as compared to cells grown at 30°C (Figure 1A, gyrB(Ts) ΔtopA, 37°C vs 30°C). We tested the effect of RNase HI overproduction on chromosome segregation in the gyrB(Ts) ΔtopA strain grown at 30°C. It did not correct the chromosome segregation defect (gyrB(Ts) ΔtopA/pSK760). Thus, we conclude that topA null cells suffer from supercoiling-dependent chromosome segregation defects that are unrelated to R-loops.

RNase HI overproduction did not correct the chromosome segregation problem whereas it clearly stimulated the growth of gyrB(Ts) ΔtopA cells at 30°C (Figure 1B, gyrB(Ts) ΔtopA vs gyrB(Ts) ΔtopA/pSK760). Therefore, at this temperature the defect was not strong enough to offset the positive effect of overproducing RNase HI. We have previously shown that RNase HI overproduction could not complement the growth defect of topA null mutants at lower temperatures. In fact, it had a negative effect [47,50]. The cold sensitivity of topA null mutants was found to be, at least in part, related to the inability of topo IV to efficiently relax negative supercoiling at low temperatures [16,17]. As a result, hypernegative supercoiling accumulated.

We found that the chromosome segregation defect of our gyrB(Ts) ΔtopA strain was exacerbated at 24°C since the cells were generally longer and the DNA more diffuse as compared to cells grown at 30°C (Figure 1A, gyrB(Ts) ΔtopA, 30°C vs 24°C). Overproducing RNase HI further stimulated cell filamentation and produced cells with large DNA-free regions (Figure 1A, gyrB(Ts) ΔtopA/pSK760, 24°C). Growth of gyrB(Ts) ΔtopA cells on solid LB medium at 24°C was very poor whether RNase HI was overproduced or not (Figure 1B, 24°C). Thus, the cold sensitivity of topA null cells triggered by excessive hypernegative supercoiling correlates with a strong chromosome segregation defect that seems to be exacerbated by RNase HI overproduction.

Topo III overproduction and recA or recQ deletions correct both the growth and chromosome segregation defects in cells lacking topo I activity

Topo III overproduction was previously shown to correct the growth defect of topA null mutants at low temperatures [47]. In fact, unlike RNase HI, topo III overproduction was able to correct the growth defect of gyrB(Ts) ΔtopA cells at 21°C [47]. Since topo III is a potent decatenase and because the growth defect of gyrB(Ts) ΔtopA cells at 24°C correlates with a strong chromosome supercoiling problem (Figure 1A), topo III overproduction may have complemented by correcting this segregation defect.

This was confirmed by the observation that overproducing topo III almost fully, at 30°C, or partially, at 24°C, corrected the chromosome segregation defect of gyrB(Ts) ΔtopA cells (gyrB(Ts) ΔtopA/pPH1243; Figure 2A, at 30°C the nucleoids are well separated and compact; at 24°C some nucleoids separated, shorter cells and the DNA is more compact as compared to cells not overproducing topo III). As expected, topo III overproduction also promoted growth on solid media at these temperatures (Figure 2B). Thus, topo III overproduction corrects the growth defect of topA null mutants, at least in part, by facilitating chromosome segregation.

The next series of experiments were performed to test the hypothesis that, as is the case in eukaryotic cells, E. coli type IA topoisomes can act with RecQ to resolve RecA-generated recombination intermediates. We first tested the effect of deleting recQ on growth and chromosome segregation in topA null cells. We found that deleting recQ was as good as overproducing topo III in correcting the growth defect of our gyrB(Ts) ΔtopA strain at both 30 and 24°C (Figure 2B; gyrB(Ts) ΔtopA ΔrecQ; western blot experiments showed that topo IV was not overproduced in the topA null strain lacking recQ; Figure S3). Deleting recQ also partially corrected the chromosome segregation defect at these temperatures (Figure 2A). Thus, our results suggest that recQ and topB act in a pathway that is related to chromosome segregation in the absence of topA.

We next tested the effect of deleting recA on growth and chromosome segregation in topA null cells. The deletion of recA partially corrected the growth defect of our gyrB(Ts) ΔtopA strain at both 30 and 24°C (Figure 2B; gyrB(Ts) ΔtopA ΔrecA), though the effect was not as good as the one conferred by deleting recQ or overproducing topo III (Figure 2B). In fact, the positive effect of deleting recA on the growth of topA null cells at 24°C was more readily observed after three days of incubation (Figure 2B, 72 h). Deleting recA also partially alleviated the chromosome segregation defects of topA null cells at both temperatures (Figure 2A). These results demonstrate that the chromosome segregation defects of topA null mutants are largely RecA-dependent and therefore support the involvement of homologous recombination.

In E. coli, positive effects of deleting recQ on growth and chromosome segregation are often attributed to unnecessary RecA-mediated recombination via the RecFOR pathway at arrested replication forks [51,52]. In this pathway, RecQ helicase acts with RecJ, a 5′-3′ exnuclease, to provide ssDNA regions on which RecF, O and R facilitate RecA nucleoprotein filament assembly. We found that deleting recJ, recO or recR had no effect on growth and chromosome segregation in our gyrB(Ts) ΔtopA strain (Figure 2, gyrB(Ts) ΔtopA ΔrecO; data not shown for recJ and recR). This indicated that the RecFOR pathway was not involved and therefore may suggest that RecQ and type IA topoisomes act together in a RecA-dependent recombination pathway.

If indeed RecQ acts on RecA-generated recombination intermediates to generate substrates for type IA topoisomes, neither topo III overproduction nor recQ deletion should improve the growth of gyrB(Ts) ΔtopA cells lacking recA. Moreover, overproducing topo III should also have no effects on the growth of gyrB(Ts) ΔtopA ΔrecQ cells. To test these predictions, the appropriate strains were constructed and spot assays were performed. As predicted, combinations of recQ and recA deletions or of topo III overproduction and recA mutation resulted in the same growth phenotype as the recA mutation alone (Figure 3A, compare gyrB(Ts) ΔtopA ΔrecQ gyrB(Ts) ΔtopA ΔrecA and gyrB(Ts) ΔtopA ΔrecQ); Figure 3B, compare gyrB(Ts) ΔtopA ΔrecQ gyrB(Ts) ΔtopA ΔrecA; Figure 3C, compare gyrB(Ts) ΔtopA ΔrecQ gyrB(Ts) ΔtopA ΔrecA with gyrB(Ts) ΔtopA ΔrecQ gyrB(Ts) ΔtopA ΔrecA).
Figure 1. Growth and chromosome segregation defects in the gyB(Ts) ΔtopA strain. (a) Representative superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at the indicated temperatures, as described in Materials and Methods. Size bars are 5 μm. Additional images are shown in Figure S1 and S2. (b) Spot tests were performed at the indicated temperatures. The LB plates were incubated for the indicated times. The strains used are RFM475 (gyB(Ts)), RFM445 (gyB(Ts)) and VU287 (RFM475/pSK760). pSK760 carries the rnhA gene for RNase HI overproduction.

Figure 2. Topo III overproduction, and recA and recQ deletions complement the growth and chromosome segregation defects in the gyrB(Ts) ΔtopA strain. (a) Representative superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at the indicated temperatures as described in Materials and Methods. Size bars are 5 μm. Additional images are shown in Figure S1 and S2. (b) Spot tests were performed at the indicated temperatures. The LB plates were incubated for the indicated times. The strains used are all derivatives of RFM475 (ΔtopA gyrB(Ts)) except SB264 which is a derivative of RFM445 (gyrB(Ts)). They are: CT150 (RFM475 ΔrecQ), VU118 (RFM475/pPH1243), SB265 (RFM475 ΔrecA), VU454 (RFM475 ΔrecO) and SB264 (RFM445 ΔrecA). Cells carrying pPH1243 were grown in the presence of IPTG to overproduce topo III. doi:10.1371/journal.pgen.1004543.g002
Overproduction of topo III, along with the deletion of recQ, was found to be epistatic to deletion of recA in correcting the growth defect of the topA gyrB(Ts) strain. Our microarray results indicated that the SOS response was constitutively expressed in our gyrB(Ts) topA strain and therefore that RecA was overproduced (not shown). The lexA3 allele was used to test the effect of the SOS response on the growth of the gyrB(Ts) topA strain. This allele makes the SOS response non-inducible and therefore considerably reduces the amount of RecA proteins produced. The lexA3 allele was found to be slightly better than deleting recA to improve the growth of the gyrB(Ts) topA strain (Figure 3D, compare gyrB(Ts) topA, gyrB(Ts) topA lexA3 with gyrB(Ts) topA lexA3).
and gyrB(Ts) ΔtopA ΔrecA; several lexA3 transductants were tested and were found to behave the same way). This result may suggest that the major effect of the recA mutation on the growth of the gyrB(Ts) ΔtopA strain was not related to the silencing of the SOS response but rather to the inactivation of the recombination function of RecA. If this is true, the lexA3 allele should behave differently from the recA mutation when combined with the recQ mutation in the gyrB(Ts) ΔtopA strain. Figure 3E shows that it was indeed the case. Whereas the recA growth phenotype was dominant over the recQ one (Figure 3A), the reverse was observed for the lexA3 allele i.e., the gyrB(Ts) ΔtopA ΔrecQ lexA3 strain grew like the gyrB(Ts) ΔtopA ΔrecQ one (Figure 3E). Thus, these results indicate that the lexA3 allele improved the growth of the gyrB(Ts) ΔtopA strain mostly by reducing the amount of RecA proteins, but at the same time that a minimal level of RecA-dependent recombination was required for the optimal growth of the gyrB(Ts) ΔtopA strain.

Our results showed that the RecF pathway for the loading of RecA on ssDNA was not involved in the RecA effects in the gyrB(Ts) ΔtopA strain (Figure 2). The RecBCD pathway is the other one involved in the loading of RecA on ssDNA in E. coli. The introduction of a recB::Tn10 mutation in our gyrB(Ts) ΔtopA strain resulted in a strain that grew very poorly. Growth inhibition was clearly observed at 37°C, a temperature normally fully permissive for the growth of the gyrB(Ts) ΔtopA strain (Figure 3F, compare gyrB(Ts) ΔtopA and gyrB(Ts) ΔtopA recB). At 30°C, growth was barely detected (Figure 3F) and the strain did not show growth at 24°C even after 6 days of incubation. These results indicate that the RecA effects in the gyrB(Ts) ΔtopA strain are most likely mediated through the RecBCD pathway and, more importantly, that a RecA-independent RecB function is required for the survival of the gyrB(Ts) ΔtopA strain. Such a RecB function has been linked to replication fork regression that can occur when forks are stalled [53,54]. Thus, these results may suggest that replication is problematic in the gyrB(Ts) ΔtopA strain. This is supported by the results presented below.

An oriC::aph mutation still oriC competent in topA null but not in isogenic topA+ cells complements both the growth and chromosome segregation defects

Our data suggested that hypernegative supercoiling in topA null mutants triggered RecA-dependent recombination that led to the accumulation of RecQ-processed intermediates. Without a sufficient amount of type 1A topo activity to resolve these intermediates, chromosome segregation could not occur. However, how excess negative supercoiling stimulated RecA-dependent recombination to a level that caused chromosome segregation defects is unclear.

We have recently used a Tn5 mutagenesis system to isolate genetic suppressors of the growth defect of a gyrB(Ts) ΔtopA ΔnhA strain (Materials and Methods; Usongo and Drolet, manuscript in preparation). The growth defect of this strain was previously shown to be related to chromosome segregation problems that could be corrected by overproducing topo III [17]. Improving gyrase activity also suppressed the chromosome segregation defects [17]. Moreover, our study of replication in this mutant led us to speculate that unregulated replication either from oriC or R-loops, or from both, could contribute to the segregation defects [34]. In agreement with this hypothesis, insertion mutants were found in loci involved in replication.

In one mutant, the kan' cassette was found to be inserted within the oriC region, close to the middle (Figure 4A, aph). It was possible that the suppressed strain could survive without an active oriC region, as replication could occur from R-loops due to the absence of the nhA gene (constitutive stable DNA replication, cSDR) [55]. Therefore, to verify if this oriC15::aph mutation was still competent for replication initiation, we tried to introduce it in wild-type (RFM443, gyrB(Ts) (RFM443) and gyrB(Ts) ΔtopA (RFM475) isogenic strains. Kanamycin resistant transductants were readily observed for the gyrB(Ts) ΔtopA strain. Southern blot analysis confirmed that the gyrB(Ts) ΔtopA transductants carried the mutated but not the wild-type oriC region (Figure S4, RFM475 ΔoriC15:aph). The few kanamycin resistant transductants of the wild-type and gyrB(Ts) strains were found to be false-positives as they were clearly observed at 37°C for the survival of the strain (Figure S4, a false positive RFM443 kan'). Repeated transduction experiments yielded similar results. Therefore, we concluded that the oriC15::aph mutation was viable only when the topA gene was absent.

Our finding that overproducing RNase HI had no effect on the growth of the gyrB(Ts) ΔtopA strain carrying the oriC15::aph mutation (at 37 and 41°C, not shown), indicated that this strain does not replicate its chromosome via cSDR. This is in agreement with a previous report showing that, as opposed to an nhA null mutant, a topA null mutant could not survive without a functional oriC/DnaA system [27]. Therefore, our topA null mutant most likely uses the oriC15::aph allele to initiate the replication of its chromosome. However, we can predict that this allele would be less active than a wild-type one and therefore should be able to complement the growth defect of a strain in which excess replication from oriC is growth inhibitory. The dnaACos mutant, isolated as an intragenic suppressor of a dnaA46 mutant, fails to grow at 30°C and below, because of excessive replication initiation from oriC [56]. A dnaACos strain carrying the oriC15::aph mutation showed good growth at both 36 and 30°C, whereas an isogenic strain with a wild-type oriC region did not (Figure S5, dnaACos oriC15::aph vs dnaACos). Thus, this result confirmed that (i) the oriC15::aph mutation is functional in replication initiation and (ii) it is less active than a wild-type oriC region.

Our results with the oriC15::aph mutation suggested that topo I may play an important role in regulating replication initiation from oriC. In a previous study, the left-half of the oriC region was shown to be essential for oriC function in vivo [57]. This section carries the DUE (DNA unwinding element, AT-rich) region from which oriC duplex melting is initiated (Figure 4A) [58]. The smallest oriC fragment found to be functional in vivo was a fragment encompassing nucleotide 1 to 163 of the oriC region (Figure 4A, oriC231). However, a wild-type strain carrying this fragment was sensitive to rich media (LB). It was concluded that the right-half of oriC was essential for multi-forked replication that is required to support high growth rates in rich media [57]. Therefore, the fact that the kan' cassette was inserted at position 142 in the oriC sequence (Figure 4A), likely explains why our oriC15::aph mutation was not functional in a wild-type strain. However, not only was the mutation oriC-competent in our topA null mutant, it apparently allowed multi-forked replication, since our gyrB(Ts) ΔtopA strain was able to grow robustly in rich media. Therefore, these results suggest that topo I plays an important regulatory role at oriC.

Flow cytometry was used in rifampicin run-out experiments with cells grown in M9 medium at 37°C to investigate the regulation of replication initiation in our strains. As recently shown [34], both wild-type and gyrB(Ts) cells contained 2nd chromosome, thus indicating that replication initiation was well regulated in these strains (Figure 4B). Cells of the gyrB(Ts) ΔtopA strain had a near perfect 2nd chromosomal pattern with one small additional peak, showing some asynchrony (Figure 4B). However, flow cytometry analysis revealed that replication initiation was not well regulated in the topA null mutant carrying the oriC15::aph mutation, as peaks reflecting 1, 2, 3, or 4 chromosomes were clearly observed
Figure 4. Replication initiation asynchrony and reduced DNA/mass ratio conferred by the oriC15::aph suppressor mutation. (a) Schematic representation of the minimal oriC region (245 bp) with its regulatory elements. DUE is the DNA unwinding element with its AT-cluster and 13-mer repeats L, M, and R (orange). DnaA binding sites: R1, R2 and R4 are high affinity sites (blue) whereas R3, R5, I1-3 and t1-2 are low affinity sites (yellow). I1-3 and t1-2 preferentially bind DnaA-ATP. IHF and FIS binding sites are also shown. For more details see [58], aph indicates the insertion site of the kan gene in the oriC15::aph insertion mutant (position 142 in the 245 bp oriC region). The oriC231 allele of Stepaniuk et al. [57] spanning the left portion of oriC up to the arrow is shown for comparison (position 163 in the 245 bp oriC region). (b) Rifampicin run-out experiments for flow cytometry analysis were performed as described in Materials and Methods. Cells were grown in M9 minimal medium. (c) DNA/mass ratios were calculated as described in Material and Methods. The strains used were: RFM443 (wild-type), RFM445 (gyrB(Ts)), RFM475 (gyrB(Ts) ΔtopA) and VU155 (RFM475 oriC15::aph). RFM475 has a significantly higher (*) DNA/mass ratio compared to RFM445 (p = 0.0199), RFM443 (p = 0.0274) and RFM475 oriC (p = 0.0292). Moreover, there is no statistical differences between the DNA/mass ratio of RFM475 oriC compared to RFM445 (p = 0.6587) and RFM443 (p = 0.8798).

Type 1A Topoisomerases in Genome Maintenance

Supercoiling- and R-loop-dependent growth and chromosome segregation defects in a gyrB(Ts) ΔtopA ΔtopB strain

We have recently shown that deleting topA could complement the growth defect of our gyrB(Ts) ΔtopA strain at non-permissive temperatures (40 to 42°C) by partially correcting its replication initiation and chromosome segregation defects [34]. However, we found that the topB gene was required for chromosome segregation and overproducing topo IV, the main cellular decatenase, could not substitute for topB. These results, and others, allowed us to conclude that topo III plays a role in replication that becomes essential when gyrase activity is defective. Here, we have confirmed that recombination was not involved by showing that deleting recA or recQ did not correct the growth and chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain at a non-permissive temperature (40°C, Figure S6). Moreover, RNase HI overproduction had no effect. Thus, at non-permissive temperatures for the gyrB(Ts) allele, the growth and chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain [34] are unrelated to recombination and R-loops.

It was observed that the optimal temperature for the growth of the gyrB(Ts) ΔtopA ΔtopB strain was 37°C. Indeed, at 30°C the growth defect was found to be exacerbated (Figure 4B, gyrB(Ts) ΔtopA oriC). Highly asynchronous replication was also previously detected in a wild-type strain carrying the oriC231 mutation [57]. Flow cytometry analysis also revealed that the DNA/mass ratio was higher by roughly 40% in the gyrB(Ts) ΔtopA strain as compared to wild-type and gyrB(Ts) strains (Figure 4C). Introducing the oriC15::aph mutation into the topA null strain restored the DNA/mass ratio to the level seen in wild-type and gyrB(Ts) strains (Figure 4C). Thus, the oriC15::aph mutation caused replication initiation to be less efficient in the gyrB(Ts) ΔtopA strain as shown by the loss of regulation and the lower DNA/mass ratio.

The oriC15::aph mutation was very effective in correcting the growth defect of our gyrB(Ts) ΔtopA strain at both 30 and 24°C (Figure 5B, compare gyrB(Ts) ΔtopA and gyrB(Ts) ΔtopA oriC). This mutation also significantly corrected the chromosome segregation defects of the topA null strain at both temperatures (Figure 5A, gyrB(Ts) ΔtopA oriC). Therefore, the recA-dependent chromosome segregation defects in the topA null mutant are likely related to excess replication from oriC. We conclude that one major role of E. coli topo I in genome maintenance is to prevent over-replication originating from oriC.

The 3954bp region spanning the left portion of oriC was better, by at least two logs, when RNase HI was overproduced (Figure 6b, compare gyrB(Ts) ΔtopA ΔtopB/pSK762c). This strain also generated a higher proportion of longer cells at 30 than 37°C (Figure S7a, compare gyrB(Ts) ΔtopA ΔtopB/pSK762c, RNase HI overproduced and gyrB(Ts) ΔtopA ΔtopB). RNase HI overproduction had no effect. Thus, at non-permissive temperatures for the gyrB(Ts) allele, the growth and chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain [34] are unrelated to recombination and R-loops.
RecA-dependent but RecQ-independent growth and chromosome segregation defects in a gyrB (Ts) ΔtopA ΔtopB strain at 30°C

The deletion of recA significantly improved the growth of the gyrB(Ts) ΔtopA ΔtopB strain at 30°C, though this was not as effective as overproducing RNase HI (Figure 6B, compare gyrB(Ts) ΔtopA ΔtopB ΔrecA/pSK762c and gyrB(Ts) ΔtopA ΔtopB/pSK760). However, deleting recA was at least as effective as overproducing RNase HI in correcting the chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain (Figure 6A, compare gyrB(Ts) ΔtopA ΔtopB ΔrecA/pSK762c and gyrB(Ts) ΔtopA ΔtopB/pSK760). Furthermore, overproducing RNase HI had no effects on growth and chromosome segregation when recA was deleted (Figure 6A, compare gyrB(Ts) ΔtopA ΔtopB ΔrecA/pSK760 and gyrB(Ts) ΔtopA ΔtopB ΔrecA/pSK762c). These results demonstrate that the R-loop-dependent chromosome segregation defects in cells lacking type 1A topois are also dependent on RecA.

Unlike inactivating recA, the deletion of recQ did not correct the phenotypes of the gyrB(Ts) ΔtopA ΔtopB strain (Figure 6, compare gyrB(Ts) ΔtopA ΔtopB ΔrecQ/pSK762c and gyrB(Ts) ΔtopA ΔtopB/pSK760). However, RNase HI overproduction was still able to correct these phenotypes when recQ was absent (compare gyrB(Ts) ΔtopA ΔtopB ΔrecQ/pSK760 and gyrB(Ts) ΔtopA ΔtopB ΔrecQ/pSK762c). Thus, the RecA- and R-loop-dependent growth and chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain are not caused by the accumulation of RecQ-processed recombination intermediates that are substrates for type 1A topois.

As RecA was previously shown to be required for cSDR that initiates from R-loops [55], over-replication could possibly be the triggering event for the growth and chromosome segregation defects of the gyrB(Ts) ΔtopA ΔtopB strain. This is supported by the genetic evidence presented below.

Suppressor mutations affecting R-loop- and/or oriC-dependent replication significantly correct the growth and chromosome segregation defects in gyrB(Ts) ΔtopA ΔtopB topA20::Tn10 strains at 30°C

One of the best suppressors of the growth defect of the gyrB(Ts) ΔtopA nthA strain that displays cell filamentation and
Figure 6. Effects of RNase HI overproduction and recA and recQ deletions on cells lacking type 1A topos. (a) Representative superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at 30°C as described in Materials and Methods. Size bars are 5 μm. (b) Spot tests at 30°C. The LB plate was incubated for 24 h. The strains used are all derivative of RFM475 (gyrB(Ts) TopA). They are: VU306 (RFM475 ΔtopB/pSK760), VU333 (RFM475 ΔtopB/pSK762c), VU363 (RFM475 ΔtopB ΔrecQ/pSK760), VU365 (RFM475 ΔtopB ΔrecQ/pSK762c), VU375 (RFM475 ΔtopB ΔrecA/pSK760) and VU379 (RFM475 ΔtopB ΔrecA/pSK762c). pSK760 carries the mnaA gene for RNase HI overproduction, whereas pSK762c carries a mutated and inactive rnhA gene.

doi:10.1371/journal.pgen.1004543.g006
chromosome segregation phenotypes similar to our gyrB(Ts) topA topB strain, had the kan’ cassette inserted within the promoter region of the dnaI gene (Figure S8A). DnaI is one of the various proteins that constitute the primosome (including PriA [59]). This protein complex allows the assembly of a replisome outside of oriC. Interestingly, the first mutation found to inhibit SDR mapped within dnaI [60]. The SOS-dependent form of stable DNA replication (SDR) was shown to be inhibited in this case [55]. However, the involvement of dnaI in the R-loop-dependent form of SDR (SDR) is still unknown [61]. To test this, the dnaI8::aph mutation was introduced in a dnaA6(Ts) strain also carrying an rnhA null mutation. The absence of RNase HI allows the dnaA6(Ts) strain to grow at 42°C as it can replicate its chromosome from R-loops (Figure 7A and B). Therefore, the fact that the dnaI8::aph allele inhibited the growth of the dnaA6(Ts) rnhA strain at 42°C, indicated that the dnaI gene was required for cSDR (Figure 7C, 42°C, compare rnhA dnaA6 and rnhA dnaA6 dnaI).

The dnaI8::aph mutation was also found to partially correct the chromosome segregation defects of the gyrB(Ts) topA topB strain (Figure S9). This suggested that replication from R-loops could, at least in part, be responsible for these problems. We therefore tested the ability of the dnaI8::aph mutation to correct similar defects in cells lacking type 1A topos. For this purpose, a different null allele of topA, the topA20::Tn10 allele that was previously shown to behave similarly to the topA allele used in the present study, was chosen [11]. A topB gyrB(Ts) strain was used in which the topA20::Tn10 allele was either immediately introduced to obtain the topB gyrB(Ts) topA20::Tn10 control strain, or introduced after the dnaI8::aph allele to obtain the topB gyrB(Ts) dnaI8::aph topA20::Tn10 strain. The chromosome segregation defects were found to be more severe in our new topB gyrB(Ts) topA20::Tn10 strain as compared to the other one carrying the topA allele (compare Figure 6A, gyrB(Ts) topB topA20/pSK762c and Figure 6A, topB gyrB(Ts) topA20::Tn10 and data not shown). Indeed, the topB gyrB(Ts) topA20::Tn10 strain at 30°C produced almost exclusively extremely long filaments that were fully packed with diffuse DNA. This could be related to our previous observation that R-loop-related problems in the absence of topo I were more severe in strains carrying the topA20::Tn10 allele instead of the topA allele [62]. RNase HI overproduction also significantly corrected both the growth and chromosome segregation defects of our topB gyrB(Ts) topA20::Tn10 strain (Figure 6A and B, compare topB gyrB(Ts) topA20::Tn10 and topB gyrB(Ts) topA20::Tn10/pSK762c). However, at 24°C, RNase HI overproduction had no effect (Figure 6C, compare topB gyrB(Ts) topA20::Tn10/pSK762c and topB gyrB(Ts) topA20::Tn10/pSK762c). This was expected, as the cold-sensitivity of cells lacking topo I is not corrected by RNase HI overproduction (see above).

It was found that the dnaI8::aph mutation was at least as effective as RNase HI overproduction in correcting the chromosome segregation defects of the topB gyrB(Ts) topA20::Tn10 strain (Figure 6A, compare topB gyrB(Ts) dnaI8::aph topA20::Tn10, topB gyrB(Ts) topA20::Tn10/pSK762c and topB gyrB(Ts) topA20::Tn10/pSK762c). However, RNase HI overproduction was slightly better than the dnaI8::aph mutation in correcting the growth defect (Figure 6B, compare topB gyrB(Ts) dnaI8::aph topA20::Tn10/pSK762c and topB gyrB(Ts) dnaI8::aph). The dnaI8::aph also had a negative effect on the growth of the topB gyrB(Ts) dnaI8::aph strain at 37°C (Figure 6D, compare topB gyrB(Ts) dnaI8::aph topA20::Tn10 and topB gyrB(Ts) dnaI8::aph topA20::Tn10). This could be due to the presence of the gyrB(Ts) allele that was previously shown, at this semi-permissive temperature, to be incompatible with a mutation (priA null) inactivating the primosome [63]. Thus, our results support the hypothesis that the R-loop and RecA-dependent chromosome segregation defects in cells lacking type 1A topos are, at least in part, related to over-replication initiated from R-loops. The fact that the dnaI8::aph mutation slightly promoted the growth of our topB gyrB(Ts) topA20::Tn10 null mutant (Figure 5B, 30 and 24°C, compare gyrB(Ts) topA20::Tn10 dnaI8::aph topA20::Tn10), suggests that cSDR is primarily a problem for topo A null cells that is exacerbated by deleting topB. This would be consistent with the assumption that topo I is the primary type 1A topo involved in the inhibition of R-loop formation [47].

Seven different kan’ insertion mutations in the C-terminal region of RNase E, the main endoribonuclease in E. coli (Usongo and Drolet, manuscript in preparation), were found to suppress the growth defect of our topA rnhA gyrB(Ts) strain. Interestingly, experimental evidence for an interplay between RNase HI and RNase E in RNA degradation has been reported [64,65]. One of these rne mutations (rne59::aph, Figure 8C) was introduced in a dnaA6(Ts) rnhA strain to test its effect on cSDR. The presence of the rne59::aph mutation significantly reduced the ability of the dnaA6(Ts) rnhA strain to grow at 42°C (by 2 to 3 logs; Figure 7D, 42°C, rnhA dnaA6 vs rnhA dnaA6 rne59::aph). This result shows that the mutated RNase E inhibited cSDR.

A topA topB gyrB(Ts) strain was constructed, with the topA20::Tn10 allele as described above, that carried the rne59::aph mutation. The rne59::aph mutation was found to be slightly better than RNase HI overproduction to correct the growth defect of cells lacking type 1A topos (Figure 8B, compare topB gyrB(Ts) rne topA20::Tn10 and topB gyrB(Ts) topA20::Tn10/pSK762c). Furthermore, it was at least as effective as RNase HI overproduction and the dnaI8::aph mutation to correct the chromosome segregation defects in these cells (Figure 8A). Thus, our results with the rne59::aph mutation lend further support to the hypothesis that cells lacking type 1A topos suffer from excess replication originating from R-loops.

The origins of replication for cSDR (oriKs) in rnhA null mutants are mostly found within or close to the ter region where bidirectional replication initiated at oriC normally terminates [55]. Thus, the origin to terminus (oriC/ter) ratio, is expected to be lowered by the occurrence of cSDR. This is indeed what was found for the rnhA null mutant (Figure S10, RFM443 vs RFM430 rnhA::cam). The oriC/ter ratio was also similarly reduced in the topA null mutant, thus supporting the occurrence of cSDR in the absence of topo I (Figure S10, RFM475).

Several of our kan’ insertion mutations were found to reduce the expression of the holC gene (Usongo and Drolet, manuscript in preparation). In a previous study, kan’ insertion mutations that reduced the expression of the holC gene were also found to suppress the growth defect of a dnaAcos strain [66]. The holC gene encodes the χ subunit of DNA pol III, the replicative polymerase in E. coli [67]. The χ subunit interacts with SSB and this interaction was recently shown to play an important role in replisome establishment and maintenance [68]. The holC2::aph mutation was tested for its ability to suppress phenotypes of cells lacking type 1A topos. For this purpose, a topA topB gyrB(Ts) holC2::aph strain, carrying the topA20::Tn10 allele, was constructed. The holC2::aph mutation was shown to slightly correct the growth defect of cells lacking type 1A topos activity (Figure 8B and C, 30 and 24°C respectively, topB gyrB(Ts) holC topA20::Tn10 vs topB gyrB(Ts) topA20::Tn10). Both cell length and the amount of DNA were also slightly reduced (Figure 8A). The fact that holC mutations by themselves can cause filamentation and chromosome segregation defects [68], may explain why
the holC2:aph mutation only partially corrected the phenotypes of the Topo B gyrB(Ts) topA20::Tn10 strain.

The holC2:aph mutation also partially corrected the growth defect of our topA null mutant (Figure 5B, 24°C, 48 h; compare gyrB(Ts) Topo A and gyrB(Ts) Topo A holC). Moreover, in rifampicin run-out experiments, replication did not appear to be well regulated in the topA null mutant carrying the holC2:aph mutation, as peaks reflecting 1, 2, 3, or 4 chromosomes were clearly observed (Figure S11, compare gyrB(Ts) Topo A and gyrB(Ts) Topo A holC). This result supports the hypothesis that the χ subunit of pol III plays a role in replication initiation [68] and therefore suggests that initiation from oriC could also be problematic in cells lacking both type 1A topoisomerases.

**Discussion**

The work described in this manuscript, which focused on the role of type 1A topoisomerases in genome maintenance in *E. coli*, revealed new important functions in replication and chromosome segregation for both topo I and III. Before this study, not much was known about the role of these enzymes in genome maintenance as opposed to the situation for eukaryotic type 1A topoisomerases.
Figure 8. Effects of dnaT18::aph, rne59::aph and holC2::aph suppressor mutations on cells lacking type 1A topos. Representative superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at 30°C as described in Materials and Methods. Size bars are 5 μm (a). Spot tests at 30°C (b), 24°C (c) and 37°C (d). The LB plates were incubated for the indicated times. The strains used are all derivative RFM445.ΔtopB (strain VU409: gyrB(Ts), ΔtopB). They are: VU421 (VU409 topA20::Tn10), VU422 (VU409 topA20::Tn10/pSK760), VU425 (VU409 topA20::Tn10/pSK762c), VU441 (VU409 dnaT topA20::Tn10), VU469 (VU409 holC topA20::Tn10), VU473 (VU409 me topA20::Tn10). pSK760 carries the rnhA gene for RNase HI overproduction, whereas pSK762c carries a mutated and inactive rnhA gene.

doi:10.1371/journal.pgen.1004543.g008
generally believed that topo I and III have distinct cellular functions, with topo I regulating supercoiling and R-loop formation and topo III being involved in chromosome segregation during replication. Here, our results show that *E. coli* type 1A topos play major roles in genome maintenance by inhibiting inappropriate replication and, as is the case for eukaryotic type 1A enzymes, by acting with RecQ to resolve RecA-generated recombination intermediates. Furthermore, while inhibiting replication from oriC is specific to topo I that regulates supercoiling, both the prevention of over-replication from R-loops and the activity with RecQ appear to be shared by both type 1A topos. This may suggest that these two functions are the major ones for type 1A topos and that they may have been conserved throughout evolution. Below, we discuss about the newly identified functions of *E. coli* type 1A topos in this work.

**E. coli** type 1A topos and RecQ

As stated in the introduction, the strand passage activity of *E. coli* topo III, but not topo I, was shown to be strongly stimulated by RecQ in *vitro* [35–37]. This would suggest that *E. coli* topo III and RecQ can act together to maintain the stability of the genome, as shown in eukaryotic cells [69]. However, no clear evidence for such a role of topo III has been reported in *E. coli*. Recent experimental evidence points to a role for topo III in chromosome segregation related to replication and independent of RecQ ([33,34]; this work). In fact, the data presented here suggest that topo I, not topo III, is the primary type 1A topo acting with RecQ in *E. coli*. Indeed, the strong chromosome segregation and growth defects of *topA* null cells at low temperatures were shown to be partially corrected by deleting *recQ* or *recA*, independent of the RecFOR pathway and by overproducing topo III, a protein that is normally of very low abundance. Moreover, both deleting *recQ* and overproducing topo III were found to be epistatic to *recA* in correcting the growth problems. This is consistent with RecQ processing RecA-dependent recombination intermediates in such a way that they can only be resolved by a type 1A topo, as is the case in eukaryotic cells. In this context, topo III overproduction would substitute for topo I and perform the resolution, thus meaning that topo III can also perform this reaction *in vivo*.

Alternatively, in the absence of *topA*, DNA substrates for topo I may accumulate and some of them could be processed by topo III, thus leading to the depletion of this very low abundant protein. This situation would lead to the accumulation of RecQ-processed recombination intermediates, if topo III normally resolves them. However, we think that this is unlikely because while a *topA recQ* strain grow very well, deleting *topA* makes this strain very sick with phenotypes identical to those of *topA topB* null cells. If *recQ* was acting with *topB*, then deleting *topB* should have had no effect on the growth of the *topA recQ* strain. Altogether, our results are more consistent with topo I being the primary type 1A topo working with RecQ in *E. coli*.

Despite the previously observed lack of stimulation of topo I activity by RecQ in *vitro*, we still believe that these two proteins can functionally interact. Indeed, it may be that the optimal experimental conditions and/or the appropriate substrate for their functional interaction have not yet been well defined. Alternatively or additionally, the much higher abundance of topo I in *vitro* as compared to topo III may compensate for its lower level of activity with RecQ. In fact, the finding that either *E. coli* topo I expression or a *NGS1* mutation could compensate for the absence of Top3 in *S. cerevisiae* [38–40], supports the assumption that *E. coli* topo I can act with RecQ in *vitro*. Moreover, in an *in vitro* system for DHJ resolution by BLM helicase with a type 1A topo, *E. coli* topo I was shown to efficiently substitute for human topo III [70].

Hsieh and co-workers have recently obtained experimental evidence for their “unravel and unlink” model whereby BLM first melts a DNA region to which RPA protein binds and topo III acts to resolve a DHJ [1,43]. Indeed, a topo III mutant unable to physically interact with BLM was shown to partially resolve a DHJ in the presence of RPA, thus suggesting that the functions of the two proteins may be separated [43]. A similar model might also be proposed for RecQ acting with topo I, the activity of which can be stimulated by SSB [71], as the two proteins do not physically interact.

Interestingly, whereas topo I is present in all bacteria, topo III is present only in a few bacteria [72]. Therefore, if a collaboration between a type 1A topo and a RecQ-like helicase is also required in bacteria, it is not surprising that topo I performs this function. However, why such a function would be required in bacteria is currently unknown. In diploid organisms RecQ-like helicases act in concert with topo III to prevent the exchange of genetic material between DNA molecules involved in recombination (DHJ dissolution; [73]).

In the present study, it was found that inactivating *recB* almost completely inhibited the growth of our *gyrB(Ts) topA* mutant, while deleting *recA* improved its fitness. This indicated that a RecA-independent RecB function was required for the survival of the *gyrB(Ts) topA* strain. Such a RecB function has been linked to replication forks resolution that can occur when forks are stalled [53,54]. In the cell, RecB is present in the RecBCD complex that has both a recombination (RecA loading at θ sites) and a dsDNA degradation (exonuclease V) function. It has been hypothesized that upon fork reversal, a HJ is formed and degradation of the dsDNA end is initiated by RecBCD. Following the encounter of a θ site and in the presence of RecA, homologous recombination can take place, leading to the formation of a second HJ. The involvement of homologous recombination is supported by the observation that, as opposed to *recB* mutants, *recD* mutants, that lack the dsDNA degradation activity of RecBCD, can survive under conditions that promote extensive replication forks reversal if the *recA* gene is present [74,75]. Next, the two HJs can be resolved by RuvABC. Alternatively, as is the case during the process of genetic exchange in diploid organisms, we propose that RecQ can act on the two HJs to promote convergent branch migration. This would lead to the formation of a hemicatenane that must be unlinked by a type 1A topo to allow chromosome segregation. In the absence of RecA, the second HJ does not form and the dsDNA is instead degraded by the RecBCD complex up to the first HJ to produce a fork structure that is used to restart replication. In this context, RecQ does not promote the formation of hemicatenanes and, as a result, chromosome segregation is not impeded by the lack of type 1A topos activity.

Experimental evidence for replication forks reversal has been reported in *E. coli* cells carrying defective DNA helicases involved in replication (*DnaB* and *Rep*; [53,74]) and, more recently, following replication-transcription collisions [75]. We speculate that the high level of negative supercoiling in the *gyrB(Ts) topA* strain at low temperatures promotes the formation of alternative non-B DNA structures that may cause the stalling of replication forks and their reversal. Alternatively, such non-B DNA structures may first block transcription and the arrested RNA polymerases may, in turn, stop the progression of replication forks to cause their reversal. Furthermore, over-replication that occurs in this strain likely exacerbates the problem and makes the cell unable to adequately deal with the reversed forks. Clearly, more work will be required to fully characterize the role(s) of type 1A topos acting with RecQ in bacteria and to find out under which circumstances this activity would be required in various DNA transactions.
**E. coli** type 1A topois in replication

In *E. coli*, replication initiated at oriC is tightly regulated so that it occurs once and only once per cell cycle [56]. This process is synchronized with the “initiation mass”. DNA supercoiling is among the many elements, including DnaA that are required for replication initiation at oriC. Indeed, *in vitro* replication initiation necessitates that the oriC plasmid be negatively supercoiled [76]. In *vivo*, deleting *topA* was found to correct the thermo-sensitive growth of a *dnaA*(*Ts*) mutant [27] and altering gyrase supercoiling activity inhibited replication initiation from oriC [77]. Moreover, we have recently shown that a *topA* deletion could correct the replication initiation defect of a strain defective for gyrase supercoiling activity [34]. Interestingly, in a screen to isolate DnaA inhibitors a compound was recently found to rescue a *dnaA*::*cysK* mutant from lethal hyperinitiation by targeting gyrase [78]. Thus, *in vitro* and *in vivo* data demonstrate that negative DNA supercoiling is required for replication initiation from oriC.

The recent determination of the crystal structure of a truncated DnaA ortholog in complex with ssDNA supports a model whereby DnaA opens the oriC region by a direct ATP-dependent stretching mechanism [79]. This work provides the strongest evidence to date for a direct participation of DnaA in DNA melting at oriC, and is fully compatible with other elements, such as DNA supercoiling, also playing a role in this process. In a recent biochemical study, DNA fragments containing at least the left portion of oriC up to II or II (Figure 4a) were shown to be required for DnaA-ATP binding to ssDNA in the absence of torsional stress [80]. This result is totally consistent with our finding that an *oriC* region lacking these II and I2 sequences (*oriC15::aph*) is functional in a *topA* null mutant, where the negative supercoiling level is elevated, but not functional in an isogenic *topA*1 strain. Thus, our results, together with those reported in the two studies mentioned above, suggest that DNA supercoiling plays an important regulatory role at oriC.

When *topB* was deleted from a *topA* null mutant, a new growth inhibitory phenotype, again related to replication, appeared at temperatures where the *oriC*-related phenotype was attenuated. Our data suggest that this major phenotype in the absence of type 1A topois is related to replication from R-loops (cSDR). This is consistent with a major role of topo I in the inhibition of R-loop formation and with the identification of topo I, like RNase H1 [81], as a specificity factor to inhibit replication initiation at sites other than *oriC* (e.g. R-loops), in an *in vitro* system [28]. Thus, although the strong phenotype expressed such as extensive cell filamentation, unsegregated nucleoids and growth inhibition, is triggered by deleting *topB*, cSDR is probably also activated in our single *topA* mutant. This is supported by the fact that the *dnaA*118::*aph* mutation improved the growth of our *topA* mutant and by the finding that, as was the case in an *rnkA* null mutant, the *oriC* ratio was lower in this *topA* mutant as compared to a wild-type strain. However, even if cSDR is activated in *topA* null mutants, the *oriC*:DnaA system is still required in these cells to replicate the chromosome. A similar situation has been described for *recG* mutants, in which cSDR is also activated but cannot support replication of the whole chromosome [82,83].

As the strong phenotype is due to the simultaneous absence of both type 1A topois, it is likely related to similar functions performed by the two enzymes. We have previously shown that an R-loop was a hot-spot for topo III activity *in vitro* [47]. By acting on an R-looped plasmid, topo III was shown to destabilize the R-loop. As topo III can travel with the replication fork [35], it could possibly act by destabilizing R-loops blocking the progression of the replication forks. Interestingly, topo III was recently shown to prevent R-loop accumulation during transcription in mammalian cells [84]. Thus, inhibition of R-loop formation might be another important function of type 1A topois that has been conserved throughout evolution. The absence of a type 1A topo activity for decatenation (e.g. RecQ with topo I) also likely contributes to the strong chromosome segregation defects seen in cells lacking both topo I and III.

### Materials and Methods

#### Bacterial strains and plasmids

Bacterial strains used in this study are all derivatives of *E. coli* K12 and are listed in Table S1. Details on their constructions as well as the list of plasmids used in this study are also given in Table S1. Transductions with P1vir were performed as described previously [34]. PCR was used to confirm that the expected gene transfer occurred in the selected transductants.

#### Insertional mutagenesis

Insertional mutagenesis with pRL27 was performed in a *topA rnkA gyrB*(*Ts*) strain and will be described in details elsewhere (Usongo and Drolet, manuscript in preparation). Briefly, pRL27 carries a hyperactive Tn5 transposase gene under the control of the telA promoter, and an insertional cassette with a kanamycin resistance gene (*aph*) and a *pir*-dependent origin (*oriR6K*) bracketed by Tn5 inverted repeats [85]. Following electroporation of pRL27 in a *pir*-background, the *kan*' cassette inserts randomly into the chromosome. A *topA rnkA gyrB*(*Ts*)/pBAD18*rnkA* strain was electroporated with pRL27 and plated on LB containing 25 μg/ml kanamycin at 40°C, to select for suppressors that grew in the absence of arabinose (no RNase H1 produced). At this temperature, the strain does not grow because of extensive inhibition of the supercoiling activity of gyrase [17], combined with over-replication ([34] and see below). P1vir was grown on the *kan*' clones that re-grew at 40°C and each phage lysate was used to infect a *topA rnkA gyrB*(*Ts*)/pPH1243 strain, that normally grows only in the presence of IPTG, to overproduce topo III from pPH1243 [17]. Transducants were selected on LB plates containing IPTG and kanamycin (50 μg/ml) at 37°C. Transductants that re-grew in the absence of IPTG were selected for further characterization. Four of the insertion mutants, described in Figure 4 and S8, were used in the present study.

#### Spot tests

Cells from glycerol stocks were resuspended in LB to obtain an OD600 of 0.6. Five μl of 10-fold serial dilutions were then spotted on LB plates that were incubated at the indicated temperatures. The experiments were performed with cells from glycerol stocks to minimize the chance of selecting cells with compensatory mutations. However, we eventually found that similar results were obtained whether the cells were from glycerol stocks or from overnight liquid cultures (not shown).

#### Microscopy

Cells were grown overnight at 37°C in liquid LB medium supplemented with the appropriate antibiotics. Overnight cultures were diluted in LB medium to obtain an OD600 of 0.01 and grown at the indicated temperature to an OD600 of 0.8. The cells were recovered and prepared for microscopy as previously described [17]. Pictures (fluorescence (DAPI and DIC) were randomly taken with a LSM 510 Meta confocal microscope from Zeiss. The images were processed using Adobe Photoshop. Representative images are shown both in the Results and Supporting Information sections.
Flow cytometry

The procedure for flow cytometry in rifampicin run-out experiments with cells grown in M9 medium has been described [34]. The DNA/mass ratio was calculated has previously reported [34].

Supporting Information

**Figure S1** Chromosome segregation defects in a ΔtopA gyrB(Ts) strain at 30°C. Superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at 30°C, unless otherwise indicated, as described in Materials and Methods. Size bars are 5 μm. The strains used are all derivatives of RFM475 (gyrB::ΔtopA) except RFM445 (gyrB::ΔtopA). They are: Vu287 (RFM475/pSK760), Vu155 (RFM475 oriC), CT150 (RFM475 ArecQ), Vu118 (RFM475/pPH1243), SB265 (RFM475 ArecO), Vu148 (RFM475 dnaT), psk760 carries the rnhA gene for RNase HI overproduction. Cells carrying pH1243 where grown in the presence of IPTG to overproduce topo III. (PPTX)

**Figure S2** Chromosome segregation defects in a ΔtopA gyrB(Ts) strain at 24°C. Superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at 24°C, unless otherwise indicated, as described in Materials and Methods. Size bars are 5 μm. The strains used are all derivatives of RFM475 (gyrB::ΔtopA). They are: Vu287 (RFM475/pSK760), Vu155 (RFM475 oriC), CT150 (RFM475 ArecQ), Vu118 (RFM475/pPH1243) and SB265 (RFM475 ArecO), psk760 carries the rnhA gene for RNase HI overproduction. Cells carrying pH1243 where grown in the presence of IPTG to overproduce topo III. The length of approximately 150 cells was measured for each strain and the proportion of filaments (arbitrarily cells longer than 7 microns) were determined: RFM475, 76%; RFM475/pSK760, 94%; RFM475 oriC, 38%; RFM475 ArecQ, 32%; RFM475/pPH1243, 28%; RFM475 ArecA, 29%. (PPTX)

**Figure S3** Topo IV is not overproduced following the deletion of recQ in strain RFM475. Cells were grown overnight on LB plates at 37°C. Aliquots were recovered for Western blotting using anti-ParC and anti-ParE antibodies as described by Usongo et al. (2013). Strains used are RFM475 (gyrB::ΔtopA) and CT150 (RFM475 ArecQ). The result shown here is representative of three independent experiments. (Usongo V, Tanguay C, Nolent F, Bessong JE, Drolet M (2013) Interplay between type 1A topoisomerases and gyrase in chromosome segregation in Escherichia coli. J Bacteriol 195:1758–1768.). (PPTX)

**Figure S4** The oriC::Tn5 allele can be introduced within topA null but not topA+ strains. Strains were grown in LB medium to OD_{600} of 0.6 at 37°C. Genomic DNA was prepared essentially as described by Nordman et al. (2007). Following genomic DNA extraction, samples were digested with XmnI and electrophoresis was performed in 0.8% agarose in 0.5× TBE at 45 V for 24 h at room temperature. After electrophoresis, samples were transferred onto a nitrocellulose membrane (Hybond-N GE Healthcare) and incubated at room temperature. After electrophoresis, samples were transferred to a nitrocellulose membrane (Hybond-N GE Healthcare). The strains used are: RFM443 (wild-type), RFM443 kan’ (wild-type kan’; a false-positive), RFM475 (gyrB::ΔtopA) and Vu155 (RFM475 oric15::aph). (Nordman J, Skovgaard, O, Wright (2007) A novel class of mutations that affect DNA replication in E. coli. Mol Microbiol 64: 125–130.). (PPTX)

**Figure S5** The oric15::aph mutation complements the growth defect of a dnaAcos mutant at 30°C. The LB plates were incubated for the indicated time and at 30, 36 or 42°C as shown. The strains used were: KA441 (dnaAcos) and Vu194 (KA441 oric15::aph). (PPTX)

**Figure S6** No effects of recA or recQ deletions on gyrB(Ts) ΔtopA ΔtopB cells at 40°C. (a) Cells were spotted on LB plates and incubated at 40°C. The LB plates were photographed after 24 and 48 h of incubation. The strains used are all derivative of RFM475 (gyrB::ΔtopA). They are: Vu306 (RFM475 TopoB/pSK760), Vu333 (RFM475 TopoB/pSK762c), Vu363 (RFM475 TopoB ArecQ/pSK760), Vu365 (RFM475 TopoB ArecQ/pSK762c), Vu375 (RFM475 TopoB ArecA/pSK760) and Vu379 (RFM475 TopoB ArecA/pSK762c). pSK760 carries the rnhA gene for RNase HI overproduction, whereas pSK762c carries a mutated and inactive rnhA gene. CT170 (gyrB::ΔtopA TopoB), (b), Vu243 (gyrB::ΔtopA TopoB ArecA), (c) and Vu205 (gyrB::ΔtopA TopoB ArecA ArecQ), (d) cells were prepared for microscopy as described (Usongo et al., 2013). Shown are superimposed images of phase contrast and fluorescence pictures of DAPI-stained cells grown at 40°C. (Usongo V, Tanguay C, Nolent F, Bessong JE, Drolet M (2008) Interplay between type 1A topoisomerases and gyrase in chromosome segregation in Escherichia coli. J Bacteriol 195:1758–1768.). (PPTX)

**Figure S7** The phenotypes of a gyrB(Ts) ΔtopA ΔtopB strain are more severe at 30 than 37°C. (a) Cells were spotted on LB plates and incubated for 24 h at the indicated temperature. (b) Cells were prepared for microscopy as described (Usongo et al., 2013). Shown are superimposed images of phase contrast and fluorescence pictures of DAPI-stained cells grown at 30 or 37°C as indicated. The strains used are all derivative of RFM475 (gyrB::ΔtopA). They are: CT170 (RMF475 TopoB), Vu306 (CT170/pSK760) and Vu333 (CT170/pSK762c). pSK760 carries the rnhA gene for RNase HI overproduction, whereas pSK762c carries a mutated and inactive rnhA gene. (Usongo V, Tanguay C, Nolent F, Bessong JE, Drolet M (2013) Interplay between type 1A topoisomerases and gyrase in chromosome segregation in Escherichia coli. J Bacteriol 195:1758–1768.). (PPTX)

**Figure S8** aph insertion sites for three suppressor mutants used in this study. The aph insertion sites for the dnaT18::aph (a), holC2::aph (b) and rne59::aph (c) alleles are shown. For (a) and (b) we show the nucleotide sequence of the regulatory regions for dnaT (promoter has been characterized) and holC (promoter unknown) where the aph cassette was inserted. In (c) we show the functional domains of the RNase E protein. Note that the aph cassette is inserted within the protein scaffold region (position 883 for rne59::aph) that is used by RNase E to interact with other proteins to form the DNA degradosome (RhBl helicase, Endolase and PNPase) (for details see Mackie (2013)). (Mackie GA (2013) New RNase E at the interface of bacterial RNA processing and decay. Nat Rev Microbiol 11:45–47.). (PPTX)

**Figure S9** Effect of dnaT18::aph allele on the chromosome segregation defects of a topA rnhA gyrB(Ts) strain. Superimposed images of DIC and fluorescence pictures of DAPI-stained cells grown at 37°C in LB without IPTG. Size bars are 5 μm. The
strains used are all derivatives of RFM475 (gyrB/Ts) AtopA. They are: VU129 (RFM475 rnhA/pPH1243) and VU148 (VU129 rnaB). pPH1243 carries the topB gene under the control of an IPTG-inducible promoter.

**Figure S10** The ori/ter ratio is similarly reduced in strains lacking either rnhA or topA. Growth of the strains, genomic DNA extraction and cutting, and Southern blotting were performed as described in the legend to Figure S4. For the “ori” probe, the DNA fragment including the gatA gene as described in the legend to Figure S4 was used. For the “ter” probe, a DNA fragment including the cedA gene (obtained from PCR with the following primers: 5’-GTATCGGGATCCAGGGCC-3’ and 5’-GAGGC- GACGCCACAGGATG-3’) was used. Strains used were: RFM443 (wild-type), RFM445 (gyrB/Ts), RFM475 (gyrB/Ts) AtopA and PH579 (rnhA). The “ori” and “ter” bands were visualised and the signal quantified by using a Phosphorimager Typhoon 9400 and the ImageQuant software (GE Healthcare). Shown here are the results of two independent experiments.

**Figure S11** Replication initiation asynchrony conferred by the holC2::aph mutation. Rifampicin run-out experiments for flow cytometry analysis were performed as described in Materials and Methods. Cells were grown in M9 minimal medium. The strains used are: RFM445 (gyrB/Ts), RFM475 (gyrB/Ts) AtopA and VU176 (RFM475 holC2::aph).

**Table S1** *Escherichia coli* strains and plasmids used in this work. The strains were constructed as described in Material and Methods.

**Acknowledgments**

We thank Tsutomu Katayama and Justin Courcelle for bacterial strains and Kenneth Marians for antibodies. We also thank Christian Charbonneau at l’Institut de recherche en immunologie et en cancérologie for his help with microscopy, Serge Sénechal for assistance with flow cytometry, Cynthia Tanguay for constructing strain CT150 and George Szatmari for English editing.

**Author Contributions**

Conceived and designed the experiments: MD VU. Performed the experiments: VU. Analyzed the data: VU MD. Contributed reagents/materials/analysis tools: MD. Wrote the paper: MD VU.
