ABSTRACT
The rice blast fungus, Magnaporthe oryzae, is an important pathogen of rice plants. It is well known that genes encoded in the genome have different evolutionary histories that are related to their functions. Phylostratigraphy is a method that correlates the evolutionary origin of genes with evolutionary transitions. Here we applied phylostratigraphy to partition total gene content of M. oryzae into distinct classes (phylostrata), which we designated PS1 to PS7, based on estimation of their emergence time. Genes in individual phylostrata did not show significant biases in their global distribution among seven chromosomes, but at the local level, clustering of genes belonging to the same phylostratum was observed. Our phylostrata-wide analysis of genes revealed that genes in the same phylostratum tend to be similar in many physical and functional characteristics such as gene length and structure, GC contents, codon adaptation index, and level of transcription, which correlates with biological functions in evolutionary context. We also found that a significant proportion of genes in the genome are orphans, for which no orthologs can be detected in the database. Among them, we narrowed down to seven orphan genes having transcriptional and translational evidences, and showed that one of them is implicated in asexual reproduction and virulence, suggesting ongoing evolution in this fungus through lineage-specific genes. Our results provide genomic basis for linking functions of pathogenicity factors and gene emergence time.

1. Introduction
Magnaporthe oryzae is one of the best studied fungal pathogens, largely because of agricultural and food security relevance of the rice blast disease it causes, in addition to the fundamental studies that have contributed broadly to our understanding of development and pathogenesis in the fungal pathogens of plants [1,2]. M. oryzae initiates its infection on plant by disseminating asexual spore, conidium. Conidium that lands on plant leaf surface germinates and starts to develop a specialized infection structure called appressorium at the germ tube apex upon recognition of surface hardness and hydrophobicity [1,3]. Using appressorium, the fungus mechanically penetrates into and grows inside the plant tissues [4]. Such invasive growth ultimately leads to formation of visible leaf lesions, which can result in significant yield losses or even death of entire plant [5]. The genome sequences of M. oryzae isolates and related species have already provided valuable knowledge about genetic mechanisms and evolution of fungal pathogenesis [6,7]. To date, more than hundred genes implicated in fungal development and pathogenesis were identified and characterized in the fungus [8,9].

Phylostratigraphy is a method that allows researchers to study the characteristics of genes over time in the context of grouping of genes by their phylogenetic origin [10]. Phylostratigraphy is devised based on the observations that comparison of genome sequences shows that a significant proportion of genes in the genome occur only in delimited evolutionary lineages. This points out that such genes have arisen during the evolution of the corresponding lineages, potentially contributing to lineage-specific adaptation. Phylostratigraphy approaches have been used to answer interesting questions such as tracking origin of cancer genes in metazoan lineages and delineating birth of new genes [11–13]. Recently, comparative genomics for four species of Armillaria (fungal forest pathogens) took advantage of phylostratigraphic approach to show that rhizomorphs express an evolutionarily young transcriptome [14].

Supplemental data for this article can be accessed here.
Lineage-specific genes are often called orphan genes or taxonomically restricted genes, and considered to originate from two mechanisms: duplication-divergence model and de novo model. Duplication-divergence model posits that genes are duplicated and undergo fast divergence, providing raw materials for functional innovation [15]. Such duplication and rearrangement mechanisms have long been thought to be the primary driving force of gene evolution. In contrast, de novo model, which recently emerges as an additional important mechanism, predicts that genes can arise from non-coding genomic regions [16]. Lineage-specific genes are known to be involved in lineage-specific adaptations or evolutionary transitions [16,17].

Here in this study, we took advantage of phyllostigmography approach for dissection of gene repertoire in the genome of *M. oryzae*. Instead of rigorous statistical analysis, however, we applied the concept of mapping gene emergence time across a defined phylogeny. Such breakdown of genes by their evolutionary age showed that physical and functional characteristics of genes correlate with their ages. Analysis on evolutionary ages of known pathogenicity genes suggested that our efforts to understand fungal pathogenesis at the molecular level are biased toward the genes that are highly conserved among diverse organisms. Orphan genes, for which no orthologs can be found in the database, accounted for a significant fraction of *M. oryzae* genome, and yet their functions, in most cases, were obscure. We provided an example of orphan gene that are implicated in fungal pathogenicity, suggesting that at least some of the orphan genes are recent addition to the genome for evolution of fungal pathogenesis.

2. Materials and methods

2.1. Estimation of gene emergence time in the phylogenetic context

Seven different phylogenetic levels were defined, based on phylogeny in MycoCosm ([https://genome.jgi.doe.gov/programs/fungi/](https://genome.jgi.doe.gov/programs/fungi/)) [18]. We chose major evolutionary transitions leading to the *M. oryzae* lineages, resulting in seven phylogenetic strata (phylostrata). In order to estimate emergence time of protein-coding genes, the predicted protein sequences of *M. oryzae* 70–15 were obtained from MycoCosm. The protein sequences were subjected to BLASTP search against the NCBI nr database with the cutoff threshold of $1e^{-5}$ [19]. For each BLASTP hit, the taxon in which the target sequence belongs to was retrieved by using NCBI taxonomy database [20]. Subsequently, each protein sequence was assigned into one of the seven phylogenetic strata (phylostrata) to investigate major evolutionary transitions leading to the *M. oryzae* lineages. Each protein sequence was assigned into one of the seven taxonomic levels (phylostrata) if the number of total significant hits becomes equal to that of the corresponding phylostratum.

2.2. Analysis of gene structure and function

Genome annotation information was downloaded from Magnaporth Comparative Genomics Project website ([https://www.broadinstitute.org/scientific-community/science/projects/fungal-genome-initiative/magnaporthe-comparative-genomics-proj/](https://www.broadinstitute.org/scientific-community/science/projects/fungal-genome-initiative/magnaporthe-comparative-genomics-proj/)). Comparison and statistical analysis of gene structure and function were performed using packages available in R programming environment [21]. GC content and amino acid composition of proteins were analyzed using “seqinr” package. For calculation of codon adaptation index (CAI), codon table for *Magnaporthe* was downloaded from the codon usage database ([http://www.kazusa.or.jp/codon/](http://www.kazusa.or.jp/codon/)) and used for calculation of CAI in R. Hydropathy index was calculated using functions built in “Peptides” package. Gene ontology analysis was carried out using topGO package. Analyses of putative secreted proteins were performed using the data obtained from Fungal Secretome Database ([http://fsd.snu.ac.kr/](http://fsd.snu.ac.kr/)) [23].

2.3. Targeted deletion of orphan genes

For targeted deletion of orphan genes, gene deletion construct was designed for targeted replacement of ORF with hygromycin B phosphotransferase gene (HPH) cassette by homologous recombination. At least over 1 kb regions flanking the 5' and 3' of the ORF were ampliﬁed and fused to the HPH sequence by fusion PCR (Table 1 in Supplementary Material for primer information on MoHKR1 knockout). The construct was introduced to the wild-type KJ201 protoplasts by PEG-mediated transformation. Transformants were selected on solid TB3 media (0.3% yeast extract, 0.3% casamino acid, 1% glucose, 20% sucrose and 0.8% agar powder; all w/v) containing 200 ppm hygromycin B and screened by PCR to identify successful deletion mutants with a single integration event. Genetic complementation was carried out by re-introducing ORF with the aforementioned flanking regions into the mutant protoplasts together with plasmid pH99 containing the geneticin resistance marker. Complementation strains were screened first on solid TB3 medium
supplemented with 800 ppm geneticin and then by PCR.

3. Results and discussion

3.1. Phylostratigraphy of M. oryzae genome

The phylostratigraphic approach was used to estimate emergence time of each of 12,832 annotated protein-coding loci in the genome of *M. oryzae* (Figure 1 and Table 2 in Supplementary Material). Alternative splicing was not considered here in our analysis. In phylostratigraphic approach using BLASTP, e-value cutoff was set to $1\times 10^{-5}$. BLAST was shown to be sensitive enough to detect orthologs among distantly related species, and e-value threshold of $<1\times 10^{-3}$ is known to provide optimal compromise between sensitivity and accuracy [24]. Seven phylogenetic classes (phylostrata) were defined according to consensus phylogenetic relationship (https://genome.jgi.doe.gov/programs/fungi/). The first phylostratum (PS1) represents genes that underlie the basis of all cellular life, while the last phylostratum represents lineage-specific genes leading to *M. oryzae*. Intermediate phylostrata (PS2 to PS6) correspond to major evolutionary events such as split of Ascomycota fungi from Dikarya. We checked out our results by two methods. First, we examined placement of histone-modifying enzymes in phylostrata. Histone-modifying enzymes such as histone acetyltransferase (HAT), histone deacetylase (HDAC), histone demethylase (HME) should be related to evolution of eukaryotes. Our data are congruent with evolution of such eukaryotic histone-modifying system by placing these enzymes only in PS2 and PS3 (Figure 1 in Supplementary Material) [25,26]. Some of the histone-modifying enzymes in PS3 indicates that they are fungal-specific histone-modifying enzymes. Indeed, Rtt109 among them is a well-known fungal-specific histone acetyltransferase that has attracted attention as a potential anti-fungal drug target. We also examined placement of a well-characterized pathogenicity factor, DES1, which is known to be Pezizomycotina-specific [27]. We found that DES1 is located in PS6. Taken together, these results suggest that our data is reliable and accurate enough for further analyses.

Our analysis shows that approximately 42% of annotated protein-coding genes in *M. oryzae* originated from prokaryotic and eukaryotic ancestors (PS1-2) Figure 1(B). The remaining genes emerged later in evolution of *M. oryzae*. Notably, we observed high peaks during split of eukaryotes to fungal lineages (PS2-3) and split of Ascomycota to Pezizomycotina (PS5-6). A high peak is also evident in PS7, which represents all genes that evolved in lineages leading to *M. oryzae* from Pezizomycotina ancestors. In particular, genes in PS7 might represent *de novo* evolved genes, since these genes are not found even in genomes of closely related plant pathogenic fungi such as *M. poae* and *Gaeumannomyces graminis* [28].

![Figure 1. Estimation of gene emergence time through phylogenetic distribution of genes using BLASTP search. (A) Diagram summarizing the process of gene emergence time estimation. (B) Summary of phylogenetic distribution of genes according to BLASTP results. Nodes marked by gray circle represent evolutionary lineages leading to *Magnaporthe oryzae*. Phylostrata corresponding to fungal lineages were shaded with light blue. Horizontal bars represent number of genes that fall in the corresponding phylostrata.](image-url)
The PS7 genes are *M. oryzae*-specific genes, of which orthologs cannot be found in database. Such genes are called orphans in many literatures. A previous study, where the same e-value threshold was applied for identification of orphan genes, reported that there are a total of 2,740 orphan genes in *M. oryzae* genome [29], in contrast to our estimation of 1,921 orphans. This discrepancy can be attributed to the size difference in the databases used for BLASTP search: NCBI nr vs. CFGP (Comparative Fungal Genomics Platform (http://cfgp.riceblast.snu.ac.kr/)) [30]. Since NCBI nr database covers much broader taxa and also contains meta-genomic sequences, it is likely that the estimation made in our study is much more accurate than the previous one.

### 3.2. Distribution of genes across and within chromosomes

Following partitioning of protein-coding genes into the defined phylostrata, we asked if physical location of genes shows any correlation with phylostrata across and within chromosomes. Among seven chromosomes of *M. oryzae*, chromosome 2 is the longest (~8.3 Mb) and chromosome 7 is the shortest (3.4 Mb). We found that genes in each phylostrata reside on seven chromosomes in proportion to the length of individual chromosomes Figure 2(A), even though minor biases were detected in chromosome 2 and 7. For example, PS1 and PS7 genes were under-represented in chromosome 2, while PS7 genes were over-represented in chromosome 7.

We also checked if there are any biases in distribution of genes within individual chromosomes Figure 2(B). However, we were not able to detect any large blocks enriched with genes from a particular phylostratum. This suggests that gene emergence appears to be randomly scattered across and within chromosomes regardless of their emergence time during evolution of *M. oryzae*.

### 3.3. Genomic features across ages

We used phylostratigraphic assignment to assess the trends over time for several physical, transcription- and/or translation-related features of genes and their protein products. With respect to physical features, gene length, GC content, hydrophobicity and amino acid composition were examined. Gene length and GC content showed tendency to decrease gradually from “old genes” (PS1-3) to “new genes” (PS7) with some exceptions (top panel in Figure 3). However, hydrophobicity of protein products did not seem to be different among phylostrata. Unlike duplication-divergence model of gene birth, the *de novo* model predicts that younger genes should be shorter than older genes, since it is highly unlikely that proteins from new genes achieve high degree of complexity.
de novo [16]. In combination with the fact that genes are often characterized by having a higher GC content than the GC content of entire genome, observed length dependence over time suggests significant contribution of de novo gene birth to evolution of *M. oryzae* genome. Interestingly, we found that proteins encoded by orphan genes (PS7) have considerably higher cysteine residues than ones from other phylostrata (middle panel in Figure 3). High cysteine content was reported in proteins that are secreted into extracellular milieu [31], suggesting that orphan genes may be enriched with such secreted proteins. However, our analysis did not detect any particular enrichment of putative secreted proteins in PS7 (Figure 2 in Supplementary Material). It is worth noting that at least

**Figure 3.** Physical and functional features of genes across phylostrata. Top panels represent distributions of gene length, GC content and hydropathy index in different phylostrata. Middle panel shows amino acid composition in proteins according to phylostrata. Bottom panels represent distribution of codon adaptation index, transcript abundance and number of Interpro domains in proteins across phylostrata.
experimentally characterized secreted proteins were enriched in PS6 and PS7 (among 20 proteins, 11 and 3 were found in PS6 and PS7, respectively).

CAI, which measures codon usage bias, exhibited no age dependence among phylostrata [32]. Only PS7 has significantly lower CAI value distribution (bottom left panel in Figure 3). Transcript abundance in hyphal tissue, however, again showed time-dependent trend: the older genes are, the more they tend to be expressed (bottom middle panel in Figure 3). These observations may reflect degree of functional contributions that genes make to the cells. In line with this, older genes tend to have higher number of functional domains, while younger genes tend to have no or less number of domains (bottom right panel in Figure 3).

3.4. Functional implications of gene age

Given the observed trends across phylostrata, we then asked how emergence time of genes is related to their functionalities, using gene ontology (GO) analysis (Figure 4). During our analysis, we noticed that it is not practical to investigate and compare genes from all phylostrata, since there are too many combinations for comparisons, and PS5 contains too small number of genes to draw any statistically meaningful conclusion. Therefore, phylostrata were further grouped into three categories: ubiquitous, fungi, and orphan. We defined genes that are found in all cellular life forms and/or eukaryotes as ubiquitous (hereafter abbreviated as Ubi). Fungi group of genes is ones that are present only in fungal species. Orphans are M. oryzae-specific genes.

GO analysis showed that Ubi gene group is enriched with functions that are generally required for cells to be cells, such as single-organism cellular process, primary metabolic process, protein modification process, and macromolecule modification, just to name a few (top panel in Figure 4). GO terms enriched in fungi gene group fall broadly under three categories: nucleotide acid metabolism process and gene expression, developmental processes such as mycelium development, and probably secondary metabolite-related processes (middle panel in Figure 4). This might suggest that evolution of fungal species should involve expansion in metabolic capacities and gene expression regulation that are likely to be linked to fungal-specific developmental program. However, in orphan gene group, there is no enrichment of particular GO terms except single-organism process (note that p-value is greater than 0.01 in all cases but one), since orphan genes are usually lacking functional domain structures and rarely characterized so far, making it difficult for us to judge significance of our observation (bottom panel in Figure 4).

3.5. Analysis of orphan genes in fungal pathogenesis

Most of published molecular genetics studies on pathogenicity genes in M. oryzae took reverse genetics
approaches, where genes of well-characterized orthologs in other organisms are identified from *M. oryzae* genome and analyzed in the context of fungal development and pathogenesis (Figure 3 in Supplementary Material). As a result, orphan genes are rarely studied to date, although they account for considerable portion of current genome annotation. The fact that such biases are evident even in large-scale forward genetics studies (such as *Agrobacterium tumefaciens*-mediated transformation (ATMT) project) [33] suggests either that orphan genes are not actually genes encoding functional proteins or that lack of protein products encoded by orphan genes has negligible effects on overall fungal fitness. To eliminate the first possibility, we took advantage of some proteomic data that are publicly available [34–37]. For translational evidence, we combined and used these multiple published proteomics data. For transcriptional evidence, we used RNA-seq data generated for mycelia tissue [22]. When we screened for orphan genes having translational evidences, we found seven genes from our orphan gene list (Table 3 in Supplementary Material). Five among these seven genes showed no or little transcription in mycelia tissue (Table 4 in Supplementary Material), which is consistent with their translational evidences being found in germinating conidia.

To delve into their roles during fungal development and pathogenesis, we attempted targeted gene knockout approach for all seven genes. For only four genes, however, we were able to successfully construct knockout vector and obtain candidate knockout mutants (data not shown). Subsequent phenotype screening revealed that deletion of one gene, which we designated *MoHKR1*, could cause detectable phenotypic changes. Although Δ*Mohkr1* was comparable to the wild-type in radial growth Figure 5(A) and 5(B), the mutant was not able to produce as many conidia as the wild-type counterpart Figure 5(C) and was much less virulent on its host plant, rice Figure 5(D). Such defects could be complemented by introduction of wild-type copy of gene back into the mutant. To the best of our knowledge, this is the first report showing...
involvement of orphan genes in fungal pathogenesis. These data suggest that at least some orphan genes are likely to be bona fide protein-coding genes playing important, lineage-specific roles in the rice blast fungus.

3.6. Concluding remarks

In this study, we categorized entire genome into discrete classes, depending on their estimated emergence time. One major concern in our analysis is whether BLASTP is sensitive enough to detect most remote homologues. However, a previous study examining capacity of BLAST through simulation to detect proteins of diverse evolutionary rates showed that BLAST only misses homologues of extremely fast-evolving sequences [24]. Therefore, it is reasonable to assume that BLAST would not produce a particular bias toward certain phylostata.

Our data suggested that emergence time of genes over evolutionary time scale is associated with physical and functional features of the genes. We argue that this type of analysis could be a potentially powerful tool to provide evolutionary insights into genetic basis of a particular trait such as fungal pathogenesis. Although studies of fungal pathogenesis so far are biased toward highly conserved genes, other data suggest ancient origin of gene functions involved in fungal development and pathogenesis. At the same time, our study illuminates the importance of monitoring new genes (orphan genes) in predicting evolutionary trajectory of fungal pathogenesis.
