Abstract

*Trichoderma* spp. are an alternative to increase plant growth and as biological control agents of diseases. Biochar added to soil and *Trichoderma* can result in the enhancement of crop development and can aid in preventing fertilizer run-off, improving plant health, retaining soil moisture, and helping plants through drought periods. However, a knowledge gap remains regarding the combined effect of biochar and *Trichoderma* on soil quality and crop growth. The objective of the present study was to evaluate this combined effect and show a new approach of biochar as a route of *T. aureoviride* (T) inoculation. We evaluated three sources of biochar, bean husks, coffee grounds, and coffee husks, with or without T and an additional control that was devoid of biochar and T. The association of all biochar sources with T showed a significant increase in watermelon growth and soil quality. Biochar coffee grounds with T increased urease, β-glucosidase, and total organic carbon, showing the potential of this combination in these processes. Watermelon plants cultivated in soil with coffee ground biochar and T showed plant length and shoot dry biomass increases of 129% and 192%, respectively. Thus, this study found that biochar use plays an important role in the effectiveness of *T. aureoviride* applications and is a new instrument for sustainable agriculture.

**Keywords:** *Citrullus lanatus*; cycling of nutrients; microbial biomass; soil fertility; soil metabolism; vegetative growth

Introduction

Biochar is a stable product obtained from the pyrolysis of organic materials, such as rice straw, wood, manure, and leaves under a low oxygen (O₂) concentration. Originally, it was found in Amazonian regions in soil bands known as “Black Indian lands” (Saxena *et al*., 2013). During the last several years, this material has received prominence because of its potential for carbon sequestration, heavy metals adsorption, and increased
availability of phosphorus (P) in the soil because of the increase in pH and the adsorption of this nutrient on its surface (Elzobair et al., 2016; Yang et al., 2017). Biochar also increases cation exchange capacity, enzymatic activities, and water retention in soil, mitigating saline stress and improving the development of plants and microorganisms (Patel et al., 2017).

Among the microorganisms, we highlight the beneficial fungi of the genus Trichoderma, which act as agents for the biological control of phytopathogens and promote plant growth (Silva et al., 2016). Among the mechanisms conferred by these fungi is the increase in the area of root absorption because of the Trichoderma root association, resulting in a higher nutritional absorption, followed by an increase in the pathogen resistance factor (Oskiera et al., 2017). This fungus assists in conserving soils, increasing seed germination rates, mitigating abiotic interference effects, and characterizing a systemic defence accompanied by increases in soil productivity (Mendoza-Mendoza et al., 2018). The fungus T. aureoviride showed physiological and functional versatilities mentioned in previous studies, such as the capacity to produce the enzyme chitinase that acts on the cell wall of several fungi and in the direct biological control of phytopathogens (Silva et al., 2016).

Considering the ease of cultural adaptation and economic relevance, the watermelon (Citrullus lanatus Thumb. Mansf.) culture constitutes a relevant model to evaluate the effects of biochar inoculated with Trichoderma because it has a short cycle, facilitating experimental trials, and its pulp, bark, and seeds are rich in minerals, vitamins, and proteins (Poduria et al., 2013).

There are several studies relating the beneficial effects of biochar applied to soil (Patel et al., 2017; Lima et al., 2018) and the use of Trichoderma as instrument to promote plant growth or biological control (Silva et al., 2017). Nonetheless, there is still a gap in knowledge regarding the effect of the combined application of both on soil quality and plant growth. There is no report regarding the use of this combined application of biochar and Trichoderma in watermelon culture; thus, this is a pioneering study in this context. This study presents the hypothesis that biochar is a potential vehicle for inoculation of Trichoderma spp., improving several soil attributes that in turn increase crop development. Therefore, the objective of the present study was to evaluate the combined effect of biochar and T. aureoviride on the improvement of soil quality and the initial development of watermelon plants.

Materials and Methods

Trichoderma aureoviride strain and biochar application

Biochar was obtained from industrial bean and coffee residues, namely, bean husks (BH), coffee grounds (CG), and coffee husks (CH). They were charred for 10 to 12 h under oxygen-limited conditions during a slow pyrolysis process where the temperature reached 530 °C in a metallic kiln and were then sieved using a 2 mm sieve. The quality of the biochar has been assessed by Lima et al. (2018).

T. aureoviride URM 5158 isolate was obtained from the Micoteca URM collection of the Mycology Department of the Biological Sciences Center of the Federal University of Pernambuco (https://www.ufpe.br/micoteca/). The fungus conidia reactivated through three successive subcultures in an Erlenmeyer flask containing 50 ml of potato dextrose agar liquid medium, grown at 26 °C ± 2 °C for eight days. Each treatment with T. aureoviride was sprayed with 100 ml (1 ×10^6 conidia per ml) applied to each biochar source. The biochar and T. aureoviride were mixed with the soil before planting.

Experimental setup

A pot experiment was conducted in a greenhouse in Pernambuco, Brazil. The soil used for the experiment was a topsoil (the 0-20 cm layer) collected in a patch of native forest in São João (08° 48’ 34.2” S,
36° 24′ 29.3″ W) at an elevation of 705 m above the mean sea level. The soil is a typical entisol with nearly 90 % sand and less than 5 % clay with extremely low values of cation exchange capacity.

The chemical attributes of the soil and biochar before the experiment are shown in Lima et al. (2018). This soil was previously treated with a formulated fertilizer NPK (6:24:12) to prevent variations related to plant nutritional deficits. We added biochar corresponding to the application of 32 t ha⁻¹ for each biochar, considering its incorporation in the first 20 cm of the soil.

The experimental design used was completely randomized in a double factorial scheme with an additional treatment (3 × 2 + 1), with four repetitions. The first factor represented three sources of biochar, BH, CG, and CH, and the second considered inoculation (T⁺) and absence (T⁻) of T. aureoviride on these substrates. The additional treatment represented the absolute control without biochar or T. aureoviride.

We used a commercial variety of watermelon (variety ‘Vereda style’) used by the farmers in the region where the experiment was conducted. The seeds were previously treated with fungicide, and three seeds were sown per pot. Five days after emergence, thinning was performed to leave one plant per pot. The plants were irrigated daily with distilled water to maintain the soil at field capacity.

At the end of the experiment, 45 days after planting, the plants were removed to measure the diameter of the base (DIA), main branch length (LEN), shoot (SFB) and root fresh biomass (RFB), followed by their respective dry biomass after drying in a forced ventilation oven at 65 °C until reaching the consistency of the dehydrated biomasses (shoot dry biomass, SDB, and root dry biomass, RDB). The experiments were repeated two times and the means of both were showed.

After removal of the plants from the pots, soils were collected for the determination of pH values in water (1:2.5) and the content of P, Na⁺, K⁺, Ca²⁺, Mg²⁺, Al³⁺, and H⁺Al³⁺, according to the methodology of Silva (2009). The inorganic labile P, Na⁺, and K⁺ were extracted using Mehlich’s solution 1 (H₂SO₄ 0.125 mol L⁻¹ + HCl 0.5 mol L⁻¹). The P was quantified using spectrophotometric colorimetry and the Na⁺ and K⁺ were determined using flame photometry. The Ca²⁺, Mg²⁺, and Al³⁺ were extracted with a KCl 1.0 mol L⁻¹ solution; the first two were determined using atomic absorption spectrometry (Raij et al., 2001). Potential acidity (H⁺Al³⁺) was determined using calcium acetate (Ca (CH₃COO)₂; H₂O) at pH 7.0. In addition, Al³⁺ was determined via titration with NaOH 0.025 mol L⁻¹ using bromothymol blue as an indicator. In all extractions, 5.0 g of soil was used for 50 mL of extractive solution (1:10).

Total organic carbon content (TOC) was obtained using the C oxidation method in a wet form with potassium dichromate followed by determination of remaining Cr₂O₇²⁻ via titration with ammonium iron (II) sulfate (Yeomans and Bremner, 1988). The microbial biomass carbon (MBC) was determined using the methodology of irradiation (Mendonça, 2005) with the extraction carried out by the addition of 80 mL of K₂SO₄ 0.5 M to each 20 g of soil (Tate et al., 1988). The C content was determined using colorimetry (Bartlett and Ross, 1988).

The evolution of CO₂ released by microbial respiration was also measured for the calculation of soil basal respiration and the soil metabolic quotient (qCO₂) using the alkaline adsorption method. For this purpose, at the end of the experiment, the soil was maintained at 60% of field capacity based on gravimetry (Anderson and Domsch, 1985). Then, 30 g of each sample were hermetically sealed in containers to capture CO₂ with 10 mL of NaOH 0.5 M solution. After 72 h, 2 mL of BaCl₂ 10% (m/v) solution were added for total precipitation of CO₂, followed by two drops of phenolphthalein diluted in 100 mL of ethyl alcohol 95% (v/v) the determinations being carried out by titration with HCl 0.25 M).

Enzymatic soil activities were determined by estimating the gene expression of the main processes related to acidic (P. Aci) and alkaline phosphatases (P. Alk) (E.C. 3.1.3), β-glucosidase (Beta) (E.C. 3.2.1.21), and urease (Ure) (E.C. 3.5.1.5) according to the colorimetric analysis of the products released by the samples subjected to incubation in an adequate substrate (Sigma-Aldrich). The activities of P. Aci and P. Alk were estimated according to the methodology of Eivazi and Tabatabai (1977). Beta was estimated using the methodology of Eivazi and Tabatabai (1988), and Ure was estimated using the method by Kandeler and Gerber (1988). Product absorbance was measured using a spectrophotometer (Libra S22, Biochrom, Cambridge, UK).
Statistical analyses

Statistical and multivariate analyses were conducted using the R language platform (v.3.4.3, 2017) based on the data of the biometric attributes of the plants, chemicals, and enzymatic activities of the soils. Multivariate exploratory analyses including nonmetric multidimensional scaling (nMDS), analysis of similarity (ANOSIM), heatmaps, and Mantel tests were completed based on the tools of the vegan and heatmaply libraries. After adjusting the models and removing the outliers, the means, standard deviations, and variation coefficients were calculated using the doBy library. Homogeneity tests, analysis of variances (ANOVA), and comparisons between averages were completed with the balanced data, according to the tools contained in the stats, AxpDes, multicompar, and agricolae libraries. Residues from all datasets were considered normal, with the exception of SDB and K, which were adequately transformed for ANOVA.

Results

The results showed the influence of the biochar source types and *T. aureoviride* on watermelon plant attributes (Table 1), soil chemical attributes (Table 2) and metabolic pattern of the soil microbial community (Table 3).

Table 1. Watermelon plants attributes (cv. Vereda style) treated with biochar from coffee grounds (CG), coffee husks (CH), and bean husks (BH), with (+T) and without (-T) inoculation of *Trichoderma aureoviride*

LEN= plant length; DIA= diameter; SFM= shoot fresh mass; RFM= root fresh mass; SDM= shoot dry mass; RDM= root dry mass. Means followed by the same lowercase in the line (between different sources of biochar) and upper case in the column (between the effects of *Trichoderma aureoviride*), do not differ statistically by Tukey’s test at 5%. The absence of letters indicates that the means are statistically equal to the 5% level using the F test. The underlined averages differ significantly from the respective control treatments (C) by Dunnett test at 5%.
The inoculation of *T. aureoviride* with biochar also demonstrated a significant increase that was, higher than that in the control treatment, with the exception of the diameter. However, the results demonstrated a significant positive effect of *T. aureoviride* inoculation on the vegetative development of watermelon plants grown in a regolithic neosol treated using different biochar sources.

Ure= soil Urease; Beta= β-glycosidase; P.Alk= alkaline phosphatase; P.Aci=acid phosphatase activities; TOC= total organic carbon; MBC= microbial biomass carbon; qCO₂= soil metabolic quotient. Means followed by the same lowercase in the line (between different sources of biochar) and upper case in the column (between the effects of *Trichoderma aureoviride*), do not differ statistically by Tukey’s test at 5%. The absence of letters indicates that the means are statistically equal to the 5% level using the F test. The underlined averages differ significantly from the respective control treatments (C) by Dunnett test at 5%

The plant biometric variables significantly responded to both biochar type and T in contrast with the control treatment. Most of the plant parameters were strongly influenced (increased) by CG or BH and T application into the soil (Table 1). For example, the application of CG biochar with *Trichoderma aureoviride* to the soil increased the plant length, diameter, shoot fresh and dry matter and root dry matter (1.3; 1.06; 1.7;
Watermelon plants that received BH biochar with T also showed increases, mainly on DIA, RFM, and RDM (9.3 times compared to the control).

The addition of biochar, in general, increased the pH and the P, K⁺, Ca²⁺, and Mg²⁺ and decreased the H⁺Al³⁺ compared to the control. BH was also generally responsible for the higher levels of P, particularly when applied with *T. aureoviride* (increase of 4.7 times compared to the control), differing from all other treatments, with the exception of CG (T-) (Table 2). The treatments with CG and BH also contributed to a reduction in potential acidity (H⁺Al³⁺), which was higher than that of CG, in general and was closely correlated with the changes in pH. The Ca²⁺ responses to the treatments were quite varied and were the same as the treatments with CG (T⁻), CG (T⁺ and T⁻), and BH (T⁺), which were all superior to CG (T⁺) and BH (T⁻).

The chemical variables pH, Na⁺, K⁺, P, and H⁺Al³⁺ significantly responded to the isolated effect of different biochar sources, while only the pH showed a significant response to the isolated effect of T inoculation (Table 2). However, T showed a significant interaction with biochar for the variables pH, P, K⁺, Ca²⁺, and H⁺Al³⁺. The chemical attributes of the control differed from those of all the other treatments, the only exception being Na⁺ content. The application of BH with T increased P (4.7 times), Ca²⁺ (1.2 times) and Mg²⁺ (2.4 times).

Biochar applied to the soil increased Ure, except in the treatment CG (T⁺). In addition, Ure activity in soils with CH and BH was higher than that of soils with CG and the opposite was observed in Beta, with its activity being significantly more expressed in CG soils (Table 3). This was the only substrate that provided a significant increase in this activity in relation to the control, regardless of the presence of T. Beta activity was also the only variable among the metabolic attributes whose significantly increased because of the inoculation with T for all biochars, mainly the application of CG with T that increase 1.5 times the Beta activity, showing its relevant participation in the hydrolysis of carbon sources.

The activity of P. Alk showed significant responses in the interaction of biochar x T. In this manner, the treatments diversified the responses of this enzyme, emphasizing that, in soils with CG (T⁺), there was higher expression of P. Alk, significantly contrasting with CG (T⁻), with less activity (Table 3).

Soils that received CG showed superior TOC (almost 2 times) content in relation to the control treatments, CH and BH, similar to Beta (Table 3). The soil MBC significantly varied with the interaction between biochar and T because of the highest accumulation of microbial carbon in the soils with BH (T⁻), significantly contrasting BH (T⁺) and the control. The metabolic quotient (*q*CO₂) also showed varied responses, highlighting its significantly higher expression in CG. The T inoculation on CG and BH significantly increased *q*CO₂, though the inverse was observed in CG. Ordering nMDS had a low stress (Sₘ = 0.11), showing an explanation of the treatment effects (biochar and T) on the metabolic and sensory activities of chemical vectors and biometric attributes (Figure 1). A control treatment was positioned in a quadrant opposite to the vectors related to the P and the main soil bases (Mg²⁺, Ca²⁺, and K⁺), and to the growth attributes of plants, in which it showed that this treatment had the lowest values. These variables showed a higher association of BH with MBC and with Ure activity in the soil that pointed to a higher contribution of BH in nutrient accumulation and N cycling in the development of plants and soil microbial communities.
Soils treated with CG biochar showed a higher RFB and levels of H+Al³⁺, as these vectors are negatively correlated with soil pH. Because the independent vectors RFB and Al³⁺ were opposed to each other, the negative effect of the increased Al³⁺ exchangeable on the root development was reiterated, showing that the approximation between RFB and H+Al³⁺ is more related to the H⁺ concentrations in the soil and not to Al³⁺, as expected. In addition, soils with CG showed the highest responses for P. Aci, Beta, and TOC. In general, the metabolic activities of the soils with CG distanced themselves from the soils with CH and BH; these dissimilarities are primarily explained by the differences that these sources exert in soil chemical attributes.

The ANOSIM test confirmed the occurrence of strong segregations among the biometric and chemical attributes (Table 4). In general, all the attributes observed in the control distanced themselves without overlapping their correspondents in the other treatments ($R_{\text{ANOSIM}} > .75$), with the exception of the biometric attributes of plants grown on soils with CH (T-), although they have still distanced themselves ($R_{\text{ANOSIM}} = .56$, Table 4).
Table 4. Analysis of similarity of attributes from coffee grounds (CG), coffee husks (CH), and bean husks (BH) with (+T) and without (-T) inoculation of *Trichoderma aureoviride*, under cultivation of watermelon plants of the variety Vereda style

c. Chemical attribute (R-Global = 0.59; p < 0.0001)

The analyses were made through the Euclidean distance applied to the normalized matrices of the metabolic (a), biometric (b), and chemical (c) attributes. These attributes were modeled in a double factorial scheme (Y ~ biochar * T. aureoviride) and submitted to permutational multivariate analysis of variance through the Adonis pseudo-F significance test, where segregations (r²) with p ≤ .05 are significant: Metabolic (a) biochar (r² = .64, p ≤ .001), T. aureoviride (r² = .008, p ≤ .785), and biochar x T. aureoviride (r² = .10, p ≤ .021); Biometrics (b) biochar (r² = .57, p ≤ .001), T. aureoviride (r² = .09, p ≤ .003), and biochar x T. aureoviride (r² = .11, p ≤ .006); (r² = .022, p ≤ .665), and biochar x T. aureoviride (r² = .022, p ≤ .231)

Analyses of the correlations between the scores of the two major components of nMDS showed that the first relevant ordering (nMDS1) had significant positive correlations with the chemical attributes pH, P, K⁺, Ca²⁺, and Mg²⁺ and had negative correlations with Al³⁺ (Table 5). The second ordering (nMDS2) showed strong positive correlations with all biometric attributes, and were significant for LEN, SFB, SDB, and RDB (Table 5). Thus, the dispersions of the metabolic pattern of the microbial communities are primarily explained by the chemical attributes of the soil and then by the responses of the plants in terms of development because of the chemical changes in the soil.

1. Ure = soil urease; Beta = β-glycosidase; P.Alk = alkaline phosphatase; P.Aci = acid phosphatase activities; TOC = total organic carbon; MBC = microbial biomass carbon; $q$CO2 = soil metabolic quotient; LEN = plant length; DIA = diameter; SFM = shoot fresh mass; RFM = root fresh mass; SDM = shoot dry mass; RDM = root dry mass

The Mantel complementary test confirmed significant positive correlations between the metabolic and biometric attributes ($r = 0.32, \rho = 0.003$), metabolic and chemical attributes ($r = 0.53, \rho = 0.001$), and chemical and biometric attributes ($r = 0.34, \rho = 0.009$). By internally analysing these interactions through the matrices with the Pearson coefficient ($R_p$), it was possible to evaluate the degree of dependence between the variables associated with the pairs (Figure 2).
**Figure 2.** Correlations between enzymatic activities, soil chemical attributes, and biometric data of watermelon plants grown on soils under different biochar treatments with and without *Trichoderma aureoviride*. The heatmap and Pearson correlation coefficients (\( R_p \)) station were used to associate the paired samples. The underlined correlations are significant (\( \rho \leq .05 \)). In general, the Mantel test revealed significant positive correlations between soil metabolic attributes and plant biometric (\( A, r = 0.32, \rho = 0.003 \)), soil metabolic, and chemical attributes (\( B, r = .53, \rho = 0.001 \)), and chemical and biometric attributes (\( C, r = 0.34, \rho = 0.009 \)).

Urease (Ure), \( \beta \)-glycosidase (Beta), alkaline phosphatase (P.Alk), acid phosphatase (P.Aci), total organic carbon (TOC), microbial biomass carbon (MBC), soil metabolic quotient (qCO2); root dry matter (RDM) and root fresh matter (RFM), shoot dry mass (SDM), and shoot fresh matter (SFM), length (LEN) and diameter (DIA) of watermelon branches.

Regarding the interaction between metabolic and biometric attributes, soil MBC showed positive correlations with RDB, SDB, and LEN of the watermelon plants (Figure 2A). The increase in the TOC in the soil was accompanied by an increase in SFB and P. alk correlated with SDB. Metabolic and chemical attribute interactions highlighted the significant and positive correlations of soil Ure activity with pH, Mg\(^{2+}\), P, K\(^{+}\), and Ca\(^{2+}\) content and the negative correlation with H\(^+\)Al\(^{3+}\). MBC also showed positive correlations with Mg\(^{2+}\) and P (Figure 2B). Regarding the interaction between chemical and biometric attributes (Figure 2C), the significant and positive correlations of Mg\(^{2+}\) with RDB and SDB and P with SDB were highlighted. The only remaining significant correlation was between Al\(^{3+}\) and SDB, demonstrating the negative effect of exchangeable Al\(^{3+}\) on the labile P and on the growth of the aerial part of the plants.

All the metabolic variables significantly responded to the isolated effect of the biochar source, the only exception begin P. Alk. The isolated effect of *T. aureoviride* inoculation was significant only for Beta and qCO\(_2\) (metabolic attributes). However, the effect of the interaction of biochar \( \times \) T was significant for Ure, Beta, TOC, and MBC, showing the potential of this combination in these processes.

**Discussion**

The different sources of organic matter used to produce the biochar generated products with different properties, mainly in the chemical attributes of the soils that received the biochar (Figure 1). Several studies showed that biochar sources as manure, coffee bark, and bean hulls that are rich in nutrients, sawdust, pine bark, and sugar cane bagasse can provide diverse agronomic and environmental benefits such as a high content of KHCO\(_3\) and CaCO\(_3\) associated with the ash of these materials, increasing the pH and Ca\(^{2+}\) content in the soils. The soil attributes can vary by source as shown in previous studies (Domingues *et al.*, 2017; Lee *et al.*, 2017; Medeiros *et al.*, 2020).
Here, we used three different sources, two from coffee and one from bean residues, that also showed differences in these and other soil chemical attributes, confirming that biochar production source influences soil fertility. The sandy soil cultivating watermelon that received biochar CG showed fewer macronutrients because it is a thermally pre-processed source; part of its nutrients is removed after infusion into water. However, its participation in the activation of the enzymes β-glucosidase and acid phosphatase was significantly higher than that found in CH. B-glucosidase facilitates the decomposition of low molecular weight carbohydrates, producing glucose, which is fundamental in the terrestrial cycle of C to supply the energy necessary for the proliferation of soil microorganisms (Eivazi and Tabatabai, 1990). Therefore, CG was a significant stimulant of β-glucosidase producing microbial communities. Notably, the increase in the activity of this enzyme accompanied the TOC (substrate) and the activity of acid phosphatase, according to the positive and significant correlations of these variables with the second ordering of nMDS (Figure 1, Table 5).

The similarity between the expressions of β-glucosidase and acid phosphatase in soils that received CG can be explained by the fact that these enzymes mitigate the discharge of bioavailable nutrients of organic carbon and phosphorus in the soil (Sinsabaugh et al., 2014), which were stimulated by the addition of organic materials as shown in two European long-term field experiments (Böhme et al., 2005). Positive and significant correlations between phosphatases and organic carbon are already well known from a previous study (Kumari et al., 2017). However, explanations for these mechanisms are not well justified.

In view of these positions and different enzymatic expressions, the present study proposed the hypothesis that the biochar of CG selects groups of distinct microorganisms that are favoured by biochars with more nutrients available - CG and BH. The higher aggregate expression of β-glucosidase and acid phosphatase in soils with CG corroborates this assertion, as these biochars led to a higher metabolism of organic materials by microorganisms in search of energy. In addition to the nature of the carbon source from the coffee biochars, the optimal pH range provided by these sources may explain the higher enzymatic activities. Acosta-Martínez and Tabatabai (2000) studied enzymatic activity in soils under different doses of limestone in Iowa (USA) and demonstrated that the activity of acid phosphatase was significantly and negatively correlated to soil pH, with optimal performance at pH 6.5. This result corroborates that of the present study (Figure 2B), where soils with CG and BH showed a relative increase in acid phosphatase activity, contrasting with the CH biochar, which greatly increased the soil pH (Tables 2, 3).

Organic waste accounts for most of the monoester phosphates in the soil, which is among the main organic sources of P (Turner, 2008). Thus, in acidic soils with low levels of nutrients and inorganic P, microorganisms are more dependent on the P forms associated with organic materials (Gatiboni et al., 2008). However, these metabolized compounds have a high affinity for soil colloids, where most of the microbiota cannot access them (Rheinheimer et al., 2001). In this aspect, biochar is once again advantageous because it can adsorb the soil nutrients on its surface, keeping them bioavailable for incorporation by microbial biomass or plants during phenolic stages of higher energy demand (Elzobair et al., 2016; Yang et al., 2017). In addition, the fungi Trichoderma spp. can also assist in plant nutrition by promoting the solubilization of some minerals, producing phytohormones, and increasing the efficiency of water use, defence, health, and plant development (Shoresh et al., 2010; Khan and Mohiddin, 2018).

In this context, MBC showed a relationship with total organic C and with acid phosphatase through approximations between both in the heatmaps (Figure 2A, 2B) and its strong positive and significant correlations with the second nMDS axis (Table 5). This relationship was discussed in Zhu et al. (2017), in which the addition of corn straw biochar under low pyrolysis (450 °C) in a dryland corn field in Northwest China increased the microbial biomass and the activity of phosphatases. Anders et al. (2013) showed that these increases were primarily attributed to the increase in C and the nutrients provided by biochar in the soil or by root activity. The present study also showed a greater approximation of RFB gain with TOC, in addition to acid phosphatase (Figure 1). This corroborates the work by Amendola et al. (2017), who verified the increase
in organic carbon and biomass of fine roots of grapevine plants immediately after the application of only 10 t ha\(^{-1}\) of biochar.

Urease was the enzyme that most directly correlated with the soil chemical attributes (Figure 2B), which is similar to the result of Kandeler et al. (2006) in the 0-10 cm layer of a pasture soil in a semiarid region of northern Colorado (EUA, 25 a 60 NH\(^{1\circ}\) -Ng\(^{1\circ}\) 2 h\(^{-1}\)). Urease is a metalloenzyme (EC 3.5.1.5) that performs the hydrolysis of urea, releasing CO\(_2\) and NH\(_3\) with increased activity to pH 10 (Kandeler and Gerber, 1988). This explains their higher activity in soils with CH and BH, sources that increased the soil pH, tending to the optimal level of performance (pH 10). This phenomenon is primarily attributed to of Ca\(^{2+}\) and K\(^+\) carbonates, abundant in CH and BH biochar, which are also rich in P and Mg\(^{2+}\), such that the pH tends to increase along with the content of these nutrients in the soil, as its potential acidity decreases (H\(^{+}\) + Al\(^{3+}\), Figure 2B).

Notably, there are high positive and significant correlations of labile P and Mg\(^{2+}\) with CBM (Figure 2B). Regarding P, this correlation is justified by its importance as a mediator in the energy transfer processes in the form of ATP and in the synthesis of nucleic acids, phospholipids, and molecular signals in the path of enzymatic phosphorylation. Mg\(^{2+}\) is also a cofactor and fundamental regulator of countless proteins with the presence of fundamental P in its transport to the interior of the prokaryotic cells. This is explained by extracellular Mg\(^{2+}\) with ATP as cofactors of Mg\(^{2+}\) hydrolase, importing ATPase (EC 3.6.3.2), the enzyme responsible for the release of phosphate and Mg\(^{2+}\) inside cells (Tao et al., 1995). In addition, in the present study, these nutrients were the only ones that significantly affected the dry mass gain of the shoot and roots (in the case of Mg) and the fresh mass of the aerial part in the case of P (Figure 2C). In summary, the mechanisms of these interactions represent some of the several that reflect the importance of PO\(_4^{3-}\) and Mg\(^{2+}\) availability for the development of watermelon plants and associated microbial communities.

In view of the variability between the responses to the different biochar sources on the chemical and enzymatic attributes of the soils, the choice of the best source is dependent on the purpose of its use. Although the CH and BH biochars provide more labile P and bases to the soil, increasing the pH, the CG biochar is more relevant for the activation of acid phosphatase and β-glucosidase and an increase in soil organic carbon. In addition, all sources presented different relevance when considering inoculation with *Trichoderma aureoviride* (Figure 1), primarily on the development of plants (Table 1).

In general, the most significant contributions of *T. aureoviride* inoculation were the following (Table 1, 2, 3): I - increased fresh root mass, regardless of biochar; II - increased fresh and dry mass of the aerial part, in treatments with CG and BH; III - increased length of the main branches in treatments with CG; IV - increased branch diameter in treatments with CG and BH; and V - increased root dry biomass in treatments with CG and primarily with BH.

Similarly, Jalali et al. (2017) demonstrated the potential to promote Arabidopsis thaliana growth because of increased tolerance to salinity stress after inoculation with several species of *Trichoderma* spp., protecting plants against oxidative damage. Kiriga et al. (2018) also demonstrated that *Trichoderma* spp. can endophytically colonize the pineapple plant roots, protecting the culture against infestations of *Meloidogyne javanica* and fungi in the soil and increasing root mass and plant development. In general, there are numerous studies mentioning other benefits provided by several species of *Trichoderma* spp., such as increased root uptake (Oskiera et al., 2017), seed germination (Mendoza-Mendoza et al., 2018), and soil metabolic activity (Elzobair et al., 2016), among others. These references corroborate the significant increase in β-glucosidase activity as a function of *T. aureoviride* inoculation, independent of the biochar used, with greater relevance for CG (Table 3).

Considering only the chemical contributions, the greatest change was observed in soils with *T. aureoviride* inoculated with BH, where there was a significant increase in the levels of labile P (Mehlich 1) and Ca\(^{2+}\) (Table 2). Corroborating this result, Saravanakumar et al. (2013) demonstrated that all ten species of *Trichoderma* spp., isolated from the rhizosphere *Avicennia marina*, a native species of mangroves, solubilized tricalcium phosphate (Ca\(_3\)(PO\(_4\))\(_2\)). This insoluble source of P induces the synthesis of the extracellular enzyme
phytase by the isolates. The same study also showed that the re-inoculation of these isolates increased the biomass of *A. marina* cultivated in poor soil (*in vitro*) without phosphate supplementation by 19%. Thus, this reference explains the simultaneous increases in exchangeable Ca and P content in soils with *T. aureoviride* and BH, in addition to the enormous enzymatic versatility and potential of vegetal promotion of this species.

These changes in the means of the variables analyzed in response to inoculation with *T. aureoviride* are because of the physicochemical specificity of each material used as they affect soil aggregation (Amendola et al., 2017) and microbial community structure (Zhang et al., 2018).

**Conclusions**

This study showed a new approach of biochar as a route of *T. aureoviride* inoculation. Watermelon plants cultivated in soil with coffee ground biochar and inoculated with *T. aureoviride* have increased the plant length and shoot dry biomass by 129% and 192%, respectively, compared to the control. The use of *T. aureoviride* via inoculation using different biochar sources showed sufficient characteristics for the development of a biological substrate with a high potential for the development of watermelon plants and improvement in the soil quality. This is even more relevant when considering the low production costs of these substrates compared to that of chemical fertilizers.
