Abstract. Background/Aim: Postsurgical hypoparathyroidism (PostHypo) is a common complication after total thyroidectomy. We studied the risk factors associated with PostHypo. Patients and Methods: The study included 109 women, (mean age: 50.7±10.75 years), who underwent total thyroidectomy for thyroid diseases. Results: Based on the development of biochemical hypocalcemia on the first postoperative day following total thyroidectomy, (cCa<8.4 mg/dl), 37 women developed PostHypo and 72 did not. Younger age, a lower preoperative corrected calcium and the presence of parathyroid glands in the specimens were related to the development of PostHypo. Of all patients, 51.4% had a vitamin D deficiency. A parathyroid hormone (PTH) value ≤9.4 pg/ml was 84.9% sensitive and 71.4% specific to predict PostHypo on the 1st postoperative day. A 50% reduction of the PTH value on the 1st postoperative day from the preoperative level could identify patients who develop PostHypo with 76% sensitivity and 75% specificity. Conclusion: PTH postoperative measurement and its alteration from the preoperative level can be used to identify patients who are at increased risk to develop PostHypo.

Total thyroidectomy is generally a safe procedure when performed by experienced surgeons. Potential major complications of thyroid surgery include injury to the recurrent laryngeal nerve, postsurgical hypoparathyroidism (PostHypo) resulting in hypocalcemia, thyrotoxic storm and surgical site infection (1). Among these conditions, PostHypo is the most common one and often the most troubling consequence of thyroid surgery (2). PostHypo is a disorder characterized by hypocalcemia, low or inappropriately normal intact parathyroid hormone (PTH) levels, and often hyperphosphatemia (3). It results from an accidental gland injury, removal of the parathyroid glands, or their devascularization (4). PostHypo may be transient when it recovers within a few weeks or one month after thyroid surgery (5), or chronic when hypoparathyroidism persists for at least six months postoperatively (6, 7). The incidence of temporary and permanent post-surgical hypoparathyroidism is estimated between 19-38% and 0-3%, respectively (8, 9).

The aims of this present study were to correlate all the epidemiological and laboratory parameters with PostHypo, and to investigate the potential prognostic factors that are related to the development of PostHypo.

Patients and Methods

The study was conducted in compliance with the principles of the Declaration of Helsinki and was also approved by the National and Kapodistrian University of Athens Medical School (protocol number 1387/8-12-2015; NCT04146259). Detailed informed consent was signed by all patients enrolled in the study before their involvement.

Patients. A prospective cohort study was performed in 109 consecutive patients who underwent total thyroidectomy, between
All patients were female with a mean age standard deviation (SD) of 50.7±10.75 years, they were euthyroid at the time of the thyroid operation and were operated by three different experienced surgeons in our department.

Inclusion criteria. In general, a total thyroidectomy is performed when there is a suspicion for papillary or medullary thyroid carcinoma (10). Indications for surgery were: i) multinodular goiter with cold nodules (n=48), ii) nodular goiter (n=28), iii) substernal goiter producing pressing symptoms in adjacent tissues (n=8), iv) Graves’ disease resistant to therapy (n=3), and v) a Bethesda result (B) higher or equal to III (B≥III) in the pathology report of the fine needle aspiration cytology (FNAC) (n=22). The FNAC results for B in all patients were: i) BI in 20 patients (18.35%), ii) BI in 67 (61.47%), iii) BI in 7 (6.42%), iv) BIV in 1 (0.92%), v) BV in 10 (9.17%), and vi) BVI in 4 (3.67%).

Exclusion criteria. Chronic kidney disease, parathyroid disorders and patients on anti-osteoporosis therapy were excluded from the study, as well as patients with a history of long-term (more than one-month administration) or current corticosteroid use.

Sample testing. Blood collections were performed in the morning following overnight fasting, at 3 different time-points: i) one day before thyroid surgery, ii) on the 1st postoperative day and iii) on the 7th postoperative day. Factors determined were: i) 25(OH)VitD, ii) PTH, iii) corrected calcium (cCa), iv) calcium (Ca), v) phosphorus (P), vi) creatinine, vii) alkaline phosphatase, and viii) albumin. Calcium levels were reported as cCa for albumin levels, using the equation:

\[ [cCa] = [Ca] + ([4-albumin] * 0.8) \]

Additional blood samples were taken from the patients in case of symptoms suggestive of hypocalcemia. All blood collections were centrifuged and serum aliquots were stored at -70°C until tested, except from Ca, P, creatinine, alkaline phosphatase and albumin measurements, which were directly analyzed on the same day in the laboratory. Total 25(OH)VitD was measured with an Electrochemiluminescence immunoassay on cobas E411 (Roche Diagnostics, Mannheim, Germany). The assay has a sensitivity of 5 ng/ml. The total analytical imprecision of this assay in our laboratory is less than 10%. The bias of the assay was monitored by the participation of our laboratory in the Vitamin D external quality assessment scheme (DEQAS) program. Intact PTH was measured by a second - generation Electrochemiluminescence immunoassay on cobas E411. The assay has a sensitivity of 1.2 pg/ml. The total analytical imprecision of this assay in our laboratory is less than 3.5%. Serum levels of Ca, P, albumin, alkaline phosphatase and creatinine were measured using a photometric method on Architect c16000 Clinical Chemistry Analyzer, (Abbott Diagnostics, North Chicago, IL, USA).

Data from the patients’ groups, including baseline levels of PTH, cCa, 25(OH)VitD, the first postoperative day absolute values of P and PTH and % changes of circulating PTH, cCa, Ca and P were estimated as follows:

\[
\Delta \text{PTH} = \frac{[\text{PTH}_1 - \text{PTH}_0]}{\text{PTH}_0} \times 100
\]

\[
\Delta \text{Ca} = \frac{[\text{Ca}_1 - \text{Ca}_0]}{\text{Ca}_0} \times 100
\]

\[
\Delta \text{P} = \frac{[\text{P}_1 - \text{P}_0]}{\text{P}_0} \times 100
\]

All values were plotted as ROC curves.

Statistical analysis. Data are presented as mean±SD for continuous variables and as frequencies (%) for categorical variables. Changes of the variables during the observation period were analyzed using one-way analysis of variance (ANOVA) for repeated measurements, while pairwise differences were analyzed using the Bonferroni test.

Groups’ differences were analyzed with the Analysis of covariance model (ANCOVA) using the group as a factor and the age as a covariate. Bivariate correlations were estimated using the Spearman’s rank correlation test. All tests were two-sided and the statistical significance was set at p<0.05.

All analyses were carried out using the statistical package SPSS, version 21.00 (IBM Corporation, Somers, NY, USA).

Results

Baseline demographic characteristics and preoperative biochemical parameters are shown in Tables I and II. The two groups were comparable according to i) weight, ii) height, iii) body mass index and iv) menopausal status.

Patients that developed hypocalcemia (Group B) were younger (Group A: 52.3±10.82 vs. Group B: 47.51±10.00 years old, p=0.03), and had lower baseline cCa levels as
compared with controls (Group A: 9.17±0.31 mg/dl vs. Group B: 8.99±0.39 mg/dl, p=0.01).

All other variables were comparable between the two groups. More than half of all patients (51.4%) had a 25(OH)D deficiency (<20 ng/ml) (Table I).

Concerning the pathology results, the number of parathyroid glands present in the specimens was the only clinical characteristic that showed a statistically significant difference between the two Groups (p=0.017). Specifically, in Group A the number of parathyroid glands found in the specimens was: i) 0 glands in 20 patients (54%), ii) 1 gland in 14 (37.8%), iii) 2 glands in 1 (2.7%) and iv) 3 glands in 2 (5.5%). None other feature, including preoperative sonographic characteristics, Hashimoto’s thyroiditis, FNAC, pathology report and weight of specimen was different between the two Groups, (p>0.05) (Table II).

Changes in serum cCa, P, PTH levels during the observation period. On the 1st postoperative day, the mean cCa dropped to 8.86±0.32 mg/dl in Group A and to 7.898±0.31 mg/dl in Group B. Patients in Group B had a significantly lower cCa value on the 1st postoperative day compared to group A (p<0.001). Calcium supplements and VitD analogues were given to patients with PostHypo in Group B in individualized doses, whereas Group A managed to increase their Ca levels after 7 days without the need for oral supplementation. All the patients had higher cCa levels on the 7th postoperative day, 9.352±0.55 mg/dl in Group A and 9.593±0.87 mg/dl in Group B, (p<0.05) (Figure 1).

Concerning P levels, there was no significant difference in the preoperative values between the two groups (Group A: 3.48±0.48 mg/dl vs Group B: 3.54±0.60 mg/dl, p=0.58), however, on the 1st postoperative day, P levels increased to 3.79±0.72 mg/dl in Group A and 4.192±0.62 mg/dl in Group B (p<0.01). On the 7th postoperative day P levels tended to normalize in Group A in contrast with Group B, where a further increase was observed (Group A: 3.74±0.62 mg/dl vs Group B: 4.44±0.73 mg/dl) (p<0.001). Patients in Group B had significantly higher P levels in both days (Figure 2).

Mean preoperative PTH levels were comparable between the two Groups, (Group A: 28.49±13.54 pg/dl vs Group B: 29.13±14.88 pg/dl, p=0.82). On the first postoperative day,
PTH was reduced to 18.85±10.83 pg/dl in Group A, and to 9.94±11.92 pg/dl in Group B (p<0.001). On the 7th postoperative day PTH levels increased in Group A in contrast with Group B where a further reduction was noted: Group A: 20.04±12.87 pg/ml vs. Group B: 8.91±9.35 pg/ml (Figure 3).

In an attempt to determine the optimal values with the best combination of specificity and sensitivity, receiver operating characteristic (ROC) curves were performed. Preoperative values of cCa, Phosphorus, PTH, 25(OH)VitD as well P and ΔP from first day post operation were poor predictors of differentiation between the two Groups, as shown by the Area Under the Curve (AUC) at ≤0.7 for all. On the other hand, on the 1st postoperative day PTH, ΔPTH, ΔcCa and ΔCa were acceptable as AUC was >0.8 for all of them. The best cut-off for PTH was found to be 9.4 pg/ml with a sensitivity of 84.9% and a specificity of 71.4% (AUC=0.806, 95%CI=0.706-0.906, p=0.05). Furthermore, for ΔPTH, the ROC curve indicated that a 50% reduction on 1st postoperative day PTH from the preoperative level as the best cut-off, with a sensitivity of 76% and a specificity of 75% (AUC=0.825, 95%CI=0.733-0.917, p=0.047). In addition, for the ΔcCa levels, the ROC curve indicated a 7% decrease in cCa one day post operation as the best cut-off, with a sensitivity of 87% and a specificity of 83% (AUC=0.922, 95%CI=0.863-0.982, p=0.030). Lastly, the best cut-off for ΔCa concentration was found to be a reduction of 11.35% in Ca 1st day post operation from preoperatively, with a sensitivity of 90% and a specificity of 83% (AUC=0.90, 95%CI=0.835-0.966, p=0.033). The clinical implementation of all these values is that the attending physician can observe them closely and, accordingly, can predict if a patient is a candidate for the development of symptoms related to PostHypo.

**Discussion**

During the past few decades there has been considerable controversy concerning the type and time of measurements performed to predict transient or permanent post-operative hypoparathyroidism. Different researchers have tried to identify a useful method to predict which patients should be administered supplemented calcium before safe hospital discharge.

Potential advantages associated with an earlier discharge are i) cost savings, ii) improved patient convenience, and iii) lower exposure to nosocomial pathogens. Hypocalcemia usually becomes noticeable between 24 and 48 h after thyroidectomy and calcium is generally measured at 6 to 12 h intervals (11). The patient can be discharged when normal corrected calcium level is achieved and an upward trend of corrected calcium is observed.

According to these issues, our study mainly focuses on the correlation of all the biochemical and demographical risk factors with the development of PostHypo and the comparison of our results with the latest data from the literature. Moreover, we suggested the optimal PTH, ΔPTH, ΔcCa and ΔCa values, according to ROC curves that can differentiate the two groups of patients.

Our study confirmed that a lower preoperative calcium level was a risk factor for PostHypo, as patients in Group B
had significantly lower cCa levels before the thyroid operation. The same finding has been confirmed by other studies in the literature (12-18). Similarly, a low postoperative Ca has been related to PostHypo, (14, 15, 19-28) as observed also in our study. Additionally, a larger decline in postoperative Calcium is also related to PostHypo (15, 20, 21, 25, 29).

Moreover, there is no consensus in the literature regarding the best time-point to test the PTH levels. The intraoperative PTH assay is widely used during parathyroid surgery (29). Intraoperative is defined as starting at time zero, which is the moment of gland excision, to skin closure at the end of the thyroid operation. The half-life of PTH is 3 minutes and its measurement is a very accurate predictor of subsequent hypocalcemia (30). It appears to be no disadvantage using intraoperative PTH measurement versus that obtained postoperatively to guide initial clinical management of serum calcium (31). In our study, PTH following surgery differed significantly between the two groups of patients. A low PTH after surgery has been related to PostHypo in many similar studies in the literature (14, 19, 20-24, 31-39) as well as a large decline of postoperative PTH (19, 32-35, 40, 41). Additionally, a great percentage (51.4%) of patients from both groups in our study had a Vitamin D deficiency with values lower than 20 ng/ml. Many other studies have confirmed the important role of Vitamin D sufficiency before thyroid surgery for the avoidance of PostHypo (37, 42, 43). A high phosphorus level following thyroidectomy is also related to the development of PostHypo in the present study, as found previously (19, 38).

In our study, hypocalcemia was significantly more common in younger patients. Previous studies have published conflicting results with respect to age as a risk factor for the development of PostHypo (6, 14, 42, 44-46). Malignant pathology was not related to PostHypo in our study, although other studies have confirmed this correlation (15, 47, 48). Also, in our study the enlarged thyroid specimen was not related significantly with the risk of PostHypo, whereas positive correlation between thyroidectomy specimens and the risk of PostHypo has been previously concluded (46). Finally, the number of identified resected parathyroid glands from the pathology analysis was related to PostHypo, in agreement with other studies in the literature (49).

Our study confirmed that PTH, ΔPTH, ΔcCa and ΔCa are parameters that best characterize patients who have a high risk for developing PostHypo. The preoperative as well as the postoperative values can be used in the clinical practice to predict which patients can be discharged from the hospital sooner and which ones should be more closely monitored for symptoms related to postsurgical hypocalcemia. We tried to predict more accurately using the ROC curves the value of PTH, ΔPTH, ΔcCa and ΔCa levels that could safely differentiate between symptomatic and asymptomatic patients. Consequently, although there are not absolute cut-off values to differentiate between the two groups, an important finding of our study was that a PTH level less than 9.4 pg/ml was 84.9% sensitive and 71.4% specific for predicting PostHypo. A drop in the parathormone value by more than 50% of the preoperative level on the 1st postoperative day had a 76% sensitivity and a 75% specificity predicting PostHypo. Accordingly, when examining Ca reduction without the correction of albumin, an 11.35% decrease of Ca between the 1st postoperative day and the preoperative value had the best combination of sensitivity (90%) and specificity (83%). Finally, a reduction of 7% in the corrected Calcium on the 1st postoperative day compared to the pre-operation value could identify patients who develop PostHypo with 87% sensitivity and 83% specificity.

Furthermore, according to our study the lower preoperative values of cCa were positively related to PostHypo, while a great percentage of patients had a VitD deficiency, which is common in Greece throughout the year (50). Therefore, we suggest a routine control of Ca metabolism for all patients who are candidates for thyroidectomy. A possible supplementation of calcium per os preoperatively could also play a protective role, while 25(OH)VitD should also be tested in patients preoperatively. In case the patient is 25(OH)VitD deficient (<20 ng/ml), a high dose of VitD could be considered. Until today, there are no consistent data concerning the preoperative VitD therapy on postoperative calcium (51, 52) and further studies are required.

Our study presents some limitations concerning the number of patients and the fact that there were recruited mostly from a single center. Also, only female patients were included so as to correlate the PostHypo to the calcium metabolism. Women are more often affected from diseases that are related to calcium metabolism, such as hyper- and hypoparathyroidism as well as osteoporosis (53, 54).

In conclusion, no absolute values of PTH or Ca were identified in our patients that could differentiate them according to their risk of developing hypocalcemia. Moreover, there is no indication about the optimal time point to control PTH and Ca and the two time points of 24 hours and 7 days are used in more often in clinical practice (3). Our study focuses in all the parameters that are related to PostHypo, including clinical characteristics as well as biochemical and hormonal results. These findings can have a clinical implementation in the everyday practice for patients undergoing total thyroidectomy, despite the fact that there is not a clear cut-off to differentiate between the two groups of patients. Importantly, the clinical decisions should be personalized for each patient separately, and all the clinical and laboratory parameters should be assessed on their own.
and in combination in order to find the patients who are at a greater risk for postsurgical hypocalcaemia. Finally, further studies including more patients of both sexes are required to identify patients at a high risk of PostHypo at an early stage.

Conflicts of Interest

The Authors report no conflicts of interest regarding this study.

Authors’ Contributions

All Authors contributed to the design and implementation of the research, the analysis of the results and the writing of the manuscript. KK carried out the experiment and the contact with the patients. KK and GP wrote the manuscript and performed the numerical calculations for the suggested experiment with support from ST and TK. Moreover, KM performed the laboratory measurements. All Authors discussed the results and contributed to the final manuscript.

Acknowledgements

The Authors would like to thank all the patients for the participation in this study and the Medical Doctors of the Head and Neck Department of Surgery at Metaxa Anti-Cancer Hospital: N. Petridis, G. Tasopoulos, P. Sarof, I. Karelas, P. Stampouloglou as well as V. Villiotou from the Biochemical Department for their valuable contribution.
