Abstract—This paper considers a multi-user downlink scheduling problem with access to the channel state information at the transmitter (CSIT) to minimize the Age-of-Information (AoI) in a non-stationary environment. The non-stationary environment is modelled using a novel adversarial framework. In this setting, we propose a greedy scheduling policy, called MA-CSIT, that takes into account the current channel state information. We establish a finite upper bound on the competitive ratio achieved by the MA-CSIT policy for a small number of users and show that the proposed policy has a better performance guarantee than a recently proposed greedy scheduler that operates without CSIT. In particular, we show that access to the additional channel state information improves the competitive ratio from 8 to 2 in the two-user case and from 18 to 8/3 in the three-user case. Finally, we carry out extensive numerical simulations to quantify the advantage of knowing CSIT in order to minimize the Age-of-Information for an arbitrary number of users.

I. INTRODUCTION

In addition to throughput, delay, and spectral efficiency, the Age-of-Information (AoI) metric has recently emerged as one of the key determinants of the Quality of Service (QoS) offered by the next-generation wireless networks. The AoI metric, first introduced in [1], measures the freshness of information available to the users in real-time. Ever since the pioneering work by Kaul et al., there has been an extensive body of work on optimizing and understanding the design implications of AoI in communication systems. See [2] for a comprehensive introduction to the recent advances in this area. In order to keep the analysis tractable, most of the existing papers on AoI assume stationary stochastic system models [3], [4]. Furthermore, the usual performance guarantees given in the literature in connection with AoI are almost always asymptotic in nature. On the contrary, applications where the AoI metric is critical to the system performance, such as the ultra-reliable low latency communication (URLLC) and mission-critical communication in cyber-physical systems, typically operate far from the stationary regime [5]. For acceptable performance, these applications also require stringent non-asymptotic upper limits on the age-of-information. To address this issue, in this paper, we focus on designing robust scheduling algorithms that ensure the maximum information freshness for the end-users, irrespective of the possibly time-varying statistics of the underlying wireless channel. In our recent papers [6], [7], [8], we introduced an adversarial version of Binary Erasure Channel (BEC) model, and showed that a greedy scheduling policy is approximately competitively optimal. These papers assume that the channel states are adversarially chosen and the scheduler does not have access to the current channel state information (CSIT). In the present paper, we extend our previous results to the setting where the channel state information of the current slot is available to the scheduler. The main objective of this paper is to quantify the provable improvement in performance due to the availability of CSIT compared to the setting when the transmitter is oblivious to the current channel state. Due to the complexity of the analysis, we only have been able to theoretically analyze the setting when the number of users (N) is either two or three. Our numerical experiments suggest the AoI advantage continues in the presence of CSIT even when the number of users is large. We anticipate that the tools and techniques developed in this paper will be useful to tackle the general problem with an arbitrary number of users. In this paper, we claim the following two main contributions:

1) For the adversarial channel model, we establish an improved upper bound on the competitive ratio for a greedy online scheduling policy that has access to the current CSIT. We show that the proposed online policy is 2-competitive when \( N = 2 \) and \( \frac{8}{3} \) \( \sim \) 2.67-competitive when \( N = 3 \). This improves the previously known tight upper-bounds on the competitive ratios (without CSIT), which are known to be 8 (for \( N = 2 \)) and 18 (for \( N = 3 \)) respectively (see Theorem 3 of [9] and Theorem 1 of [8], where the competitive ratio is bounded by \( 2N^2 \) for any \( N \geq 1 \)).

2) We numerically compare the performance of the online scheduling policy which knows channel states at the current slot with a greedy online scheduling policy which does not have the current channel state information. Our results show that the AoI is substantially reduced with CSIT.

The rest of the paper is organized as follows. In Section II we describe our adversarial system model and formulate the problem. In Section III we derive the competitive ratio of a
greedy scheduling policy for the case $N = 2$ and $N = 3$. In Section IV, we present our simulation results, and finally, in Section V, we conclude the paper with a brief discussion on possible future research directions.

II. SYSTEM MODEL AND PROBLEM FORMULATION

We consider an online scheduling problem with $N$ users located in the coverage area of a single Base Station (henceforth referred to as BS). Time is slotted, and at the beginning of every slot, a fresh update packet arrives at the BS from some external source. Such traffic models are known as the saturated traffic models in the literature [10], [11], [12]. Each of the $N$ users are interested in receiving the fresh packet at each slot to keep up-to-date with the external source. Once a fresh packet arrives, the BS beamforms and schedules a packet transmission to one of the $N$ users according to a scheduling policy $\pi$. The downlink channels from the BS to the users are assumed to be non-stationary, modeled as an adversarial binary erasure channel, whose states are dictated by an adversary. In particular, the downlink channel state for any user could be either Good or Bad as determined by the adversary. The online scheduling policy $\pi$, equipped with the channel state information (CSIT), knows the current channel states of all users before the scheduling decision for a slot is made. Making use of the current channel state information, the policy selects a user having a Good channel (if any) and then transmits the latest packet from the BS to the user. The adversary controlling the channel states may know the scheduling policy as well.

This adversarial framework was first introduced in our recent papers [6], [7], [8].

Our objective is to design a scheduling policy that competitively optimizes the average freshness of information for all the users. For any time slot $t \geq 1$, let $t_i(t)$ denotes the last time slot when the $i^{th}$ user successfully received a packet from the BS. The Age of Information (AoI) for the $i^{th}$ user at slot $t$ is defined as:

$$h_i(t) = t - t_i(t).$$

In other words, the quantity $h_i(t)$ measures the number of time slots before which the $i^{th}$ user received the last packet prior to time $t$. The $N$ dimensional vector $h(t)$ represents the collection of AoI for $N$ users at time $t$ where $i^{th}$ element of the vector refers to the AoI of the $i^{th}$ user $i.e.$ $h_i(t).$ The age $h_i(t)$ increases linearly with time until the $i^{th}$ user receives a fresh packet. Once a user receives a fresh packet, its AoI instantaneously drops to unity. See Fig. 1 for an illustration of the evolution of AoI.

Objective function: Throughout this paper, we consider optimizing the total AoI metric, which is defined as the sum of AoI cost incurred for all users over the entire time horizon under consideration. Hence, the objective function for the AoI minimization can be expressed as:

$$\text{AoI}(T) = \sum_{i=1}^{N} \sum_{t=1}^{T} h_i(t)$$

where, in the above, the supremum is taken over all possible finite length channel state sequences $\sigma$.

B. Scheduling Policies

In this paper we analyze the performance of the following online policy:

Max-Age with CSIT policy (MA-CSIT): At each time slot, the scheduler determines the current channel states of all users using the CSIT. The BS then schedules a fresh packet transmission to the user having the highest age among all users currently having a Good channel. If at any time slot, no channel is in Good state, the MA-CSIT policy does not schedule a packet transmission to any user.

Fig. 2. Timeline of MA-CSIT policy at a particular time slot

For bounding the competitive ratio of the MA-CSIT policy, we need to characterize the Offline optimal policy (OPT). The OPT policy is assumed to know the channel states of all the users for the entire time duration a priori. Hence, the performance of any other scheduling policy is dominated by that of OPT. However, the OPT policy can not be implemented in
an online fashion as it assumes the knowledge of the future channel states.

Baseline: In order to determine the benefit of having CSIT, we compare the performance of the MA-CSIT policy with the Max-Age policy that does not consider the channel state information [6, 8]. Under the Max-Age policy, at each time slot, BS schedules a fresh packet to the user which has the highest age among all the users, irrespective of the current channel states. Hence, if the channel state at the scheduled user-end turns out to be Bad, the packet is lost.

III. PERFORMANCE ANALYSIS

In this section, we bound the competitive ratio of the MA-CSIT policy from the above.

A note on determining the Max-age users: To begin with, at any time slot, we first sort the users according to descending order of their ages under the MA-CSIT policy. The user, who has the highest age among all the users (under the MA-CSIT policy) is called the Max-age user (ties are broken arbitrarily). Similarly, the mth user in the sorted list is called the mth Max-age user. Thus the Max-age user corresponds to m = 1 in the sorted list at that time slot. Naturally, under a different policy (e.g., OPT) the Max-Age user may not have the highest age among all users.

Next, we recall the concept of a time interval, first introduced in [9].

Definition 1: (Interval) A new interval is said to begin when the Max-age user transmits a packet successfully under the MA-CSIT policy.

Hence, an interval continues until the channel corresponding to the Max-age user becomes Good. Let the quantity h_{i} denote the age of the kth user at the ith time slot of the ith interval under the MA-CSIT policy. Also, let o_{i} denote the age of the kth user at the ith time slot of the ith interval under OPT policy. So h_{i} denotes the age of the kth user at the first time slot of the ith interval under the MA-CSIT policy. The length of the ith interval is denoted as I_{i} and the total AoI cost incurred by the MA-CSIT and the OPT policies on the ith interval are denoted by C_{MA-CSIT}(I_{i}) and C_{OPT}(I_{i}) respectively. With the above definitions in place, we now proceed to bound the competitive ratio of the MA-CSIT policy.

A. Competitive ratio of the MA-CSIT policy for N = 2 users

Note that, this k does not refer to the index of the user in the sorted list which is prepared at every time-slot to determine the ordering of the Max-age users on the basis of the ages of the users under the MA-CSIT policy. For example the user 1 at a certain time-slot may become the Max-age user and at another time-slot may become 2nd Max-age user and so on, but its index remains same for the time duration T for both the policies.

Proposition 1: The competitive ratio of the MA-CSIT policy for N = 2 users is upper bounded as \( \eta_{MA-CSIT} \leq 2 \).

Proof: For two users, we can express the difference between the costs incurred by the MA-CSIT policy and OPT as:

\[
C_{MA-CSIT}(I_{i}) - C_{OPT}(I_{i}) = \sum_{t} (h_{t}^{1} - o_{t}^{1}) + \sum_{t} (h_{t}^{2} - o_{t}^{2}),
\]

where the index in the summation ranges over all slots in the ith interval. We now establish the following Lemma.

Lemma 1: For the Max-age user, the age difference between the MA-CSIT policy and the OPT policy for every time slot t of the ith interval remains constant. For example, if at the ith interval the user 1 remains the Max-age user then the age difference \( (h_{t}^{1} - o_{t}^{1}) \) remains constant throughout the interval i.

Proof: Without any loss of generality, let us assume that the MA-CSIT policy serves the user 2 at the beginning of the ith interval, and at the ith interval, the user 1 becomes the Max-age user.

We establish Lemma 1 on the basis of the following observation. Both MA-CSIT and OPT policies can not serve the Max-age user until the channel corresponding to that user becomes Good. Furthermore, whenever the channel becomes Good, the MA-CSIT policy will serve the Max-age user immediately and a new interval begins. Thus, within any interval, both the quantities \( h_{i}^{1} \) and \( o_{i}^{1} \) increase linearly. Hence,

\[
h_{i}^{1} - o_{i}^{1} = h_{1}^{1} - o_{1}^{1} \quad \forall t.
\]

Since we assume that user 1 is the Max-age user at the ith interval, we have \( h_{i}^{1} > o_{i}^{1} \). The next interval, i.e., the \((i+1)th\) interval begins when the MA-CSIT policy serves user 1. Thus we have,

\[
C_{MA-CSIT}(I_{i}) = C_{OPT}(I_{i}) + (h_{1}^{1} - o_{1}^{1})I_{i} + \sum_{t} (h_{t}^{2} - o_{t}^{2})
\]

We now establish the following useful result.

Lemma 2: For the user other than the Max-age user, the age difference between the MA-CSIT and the OPT policy is always non-positive (i.e., \( h_{t}^{2} - o_{t}^{2} \leq 0 \) \( \forall t \) for this case).

Proof: To prove \( h_{t}^{2} - o_{t}^{2} \leq 0 \) \( \forall t \) we use the following facts. At the next time slots of the ith interval whenever the channel corresponding to user 2 becomes Good, both the MA-CSIT and the OPT policies serve the user 2. The only scenario when the age of user 2 under the MA-CSIT policy becomes greater than age of user 2 under OPT i.e. \( h_{t}^{2} > o_{t}^{2} \) is when
the channel corresponding to user 2 becomes Good and OPT serves the user 2 but MA-CSIT does not. In other words the OPT policy serves the user 2 while the MA-CSIT policy serves the user 1. Since we considered user 1 as the Max-age user and if the MA-CSIT policy serves the user 1, from the definition of interval the next interval i.e. (i + 1)th interval starts. This implies at the ith interval the age of the user 2 under MA-CSIT will never become more than the age under OPT. Hence,

\[ h_2^{i+1} - o_2^{i+1} < 0 \quad \forall i \]  \hspace{1cm} (6)

Combining the above two Lemmas, equation (3) may be simplified as

\[ C_{\text{MA-CSIT}}(l_i) \leq C_{\text{OPT}}(l_i) + (h_1^{i+1} - o_1^{i+1})l_i \]  \hspace{1cm} (7)

For bounding the second term in the above inequality, we need to introduce the notion of Residue-Length as defined below:

**Definition 2:** (Residue-length) The ith residue-length \( l_i \) is the length of time from the last slot in the previous interval when the Max-age user of the ith interval got served by the MA-CSIT policy, counted up to the beginning of the ith interval.

See Fig. 3 for an illustration of the intervals and the residue lengths. It is not hard to verify that the difference of the ages of the Max-age user under the MA-CSIT policy and OPT at the beginning of the ith interval can be upper bounded by the residue-length \( l_i \) i.e. \( h_1^{i+1} - o_1^{i+1} \leq l_i \). Hence, from Eqn. (7), we have the following upper bound:

\[ C_{\text{MA-CSIT}}(l_i) \leq C_{\text{OPT}}(l_i) + l_i l_i. \]  \hspace{1cm} (8)

Finally, to find an upper bound to the competitive ratio, we need to derive a lower bound of the cost of the OPT policy for each intervals. Note that, after the first time slot of any interval, the Max-age user, by definition, encounters consecutive Bad channels. Hence, the cost corresponding to that user under the OPT policy can be lower bounded by \( \sum_{k=1}^{l_i} k \).

During the ith interval, the channel corresponding to the user other than the Max-age user (i.e. user 2) does not become Good after the \((l_i - l_{i+1})th\) time slot. This fact can be verified from the definition of residue-length. Therefore, the cost for user 2 under OPT for the ith interval can be lower bounded as:

\[ \sum_{k=1}^{l_i - l_{i+1}} 1 + \sum_{k=1}^{l_{i+1}} k = l_i - l_{i+1} + \sum_{k=1}^{l_{i+1}} k. \]  \hspace{1cm} (9)

Hence, the total AoI cost under the OPT policy (including both users) for the ith interval can be lower bounded as:

\[ C_{\text{OPT}}(l_i) \geq \sum_{k=1}^{l_i} k + l_i - l_{i+1} + \sum_{k=1}^{l_{i+1}} k. \]  \hspace{1cm} (10)

Summing up the costs over all intervals we have the following bound:

\[ \sum_i C_{\text{MA-CSIT}}(l_i) \leq \sum_i C_{\text{OPT}}(l_i) + \sum_i l_i l_i. \]  \hspace{1cm} (11)

Substituting the bound from Eqn. (10) in the inequality above, we have:

\[ \frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 1 + \frac{\sum_i l_i l_i}{\sum_i (\sum_{k=1}^{l_i} k + l_i - l_{i+1} + \sum_{k=1}^{l_{i+1}} k)} \]  \hspace{1cm} (12)

Now we use the AM-GM inequality to get \( l_i l_i \leq l_i^2 + \frac{l_i^2}{2} \). Furthermore, we have \( \sum_{k=1}^{l_i} k + l_i - l_{i+1} + \sum_{k=1}^{l_{i+1}} k = \frac{l_i (l_i + 1)}{2} + l_i + (l_{i+1} (l_{i+1} + 1)) - l_{i+1} \geq \frac{l_i^2}{2} + \frac{l_i^2}{2} \). Hence,

\[ \frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 1 + \frac{l_i^2 + l_i^2}{\sum_i l_i^2 + \frac{l_i^2}{2}} \leq 2, \]  \hspace{1cm} (13)

where we have used the fact that, by definition \( l_1 = 0 \). Hence, \( \eta_{\text{MA-CSIT}} \leq 2 \).

The above result should be compared and contrasted with Theorem 3 of \([8]\), which proves an upper limit of 8 for the competitive ratio of the Max-Age policy that operates without CSIT.

In the following, we extend the above proof technique for \( N = 3 \) users. The reader will find that although the basic line of analysis remains the same, the details become much more involved in this case.

### B. Competitive ratio of the MA-CSIT policy for \( N = 3 \) users

**Proposition 2:** The competitive ratio of MA-CSIT policy for \( N = 3 \) users is upper bounded as \( \eta_{\text{MA-CSIT}} \leq \frac{8}{3} \).

**Proof:** We use the same definition of intervals as in our previous proof. The difference in the AoI costs incurred by the MA-CSIT and the OPT policies can be expressed as follows:

\[ C_{\text{MA-CSIT}}(l_i) - C_{\text{OPT}}(l_i) = \sum_i (h_1^{i+1} - o_1^{i+1}) + \sum_i (h_2^{i+1} - o_2^{i+1}) + \sum_i (h_3^{i+1} - o_3^{i+1}). \]  \hspace{1cm} (14)

where the index in the summation ranges over all slots in the ith interval. Without any loss of generality, let us assume that
user 1 is the Max-age user for the \( t \)th interval under the MA-CSIT policy. Note that Lemma 1 holds for any number of users (hence, for \( N = 3 \) also). This is because whenever the channel corresponding to the Max-age user becomes Good, the MA-CSIT policy serves that user immediately and a new interval begins. Thus, the difference of ages of the Max-age user under the MA-CSIT and OPT policies remains constant throughout any interval (as both increase linearly throughout an interval). Therefore we can write

\[
C_{\text{MA-CSIT}}(I) = C_{\text{OPT}}(I) + l_i I_i + \sum_j l_j f_j
\]

where \( f_j \) refers to the length of the \( j \)th sub-interval of the \( t \)th interval, and the index \( j \) runs over all sub-intervals of the \( t \)th interval.

Next, we proceed to lower bound the cost incurred by the OPT policy during the \( t \)th interval.

a) Lower bounding the cost of the Max-age user: Since, the \( t \)th interval continues until the channel corresponding to the Max-age user becomes Good, the cost incurred by the Max-age user (i.e. user 1 in this case) under the OPT policy is lower bounded by

\[
\sum_{k=1}^{t_i} k \geq \frac{l_i^2}{2}
\]

b) Lower bounding the cost of the 2nd Max-age user: The cost incurred by the 2nd Max-age user under the OPT policy during the \( t \)th sub-interval is \( \sum_{k=1}^{l_j} k \). This is true because for the entire duration of the \( j \)th sub-interval, the channel corresponding to the 2nd Max-age user remains Bad.

c) Lower bounding the cost of the 3rd Max-age user: Following the definition of the sub-residue lengths, the quantity \( l_{j+1} \) denotes the last time slot when the MA-CSIT policy serves the 3rd Max-age user of the \((j+1)\)th sub-interval, counted from the beginning of the \((j+1)\)th sub-interval. On the \((j+1)\)th sub-interval, the 3rd Max-age user of the \( j \)th sub-interval becomes the 2nd Max-age user. Hence, for the last \( l_{j+1} \) time slots of the \( j \)th sub-interval, the cost of the 3rd Max-age user of the \( j \)th sub-interval under the OPT policy is given by \( \sum_{k=1}^{l_{j+1}} k \).

Thus, the cost under the OPT policy during the \( j \)th sub-interval of the \( t \)th interval, excluding the cost of the Max-age user is lower bounded by:

\[
\sum_{k=1}^{l_j} k + \sum_{k=1}^{l_j} 1 + \sum_{k=1}^{l_{j+1}} k \geq \frac{(l_j^2)}{2} + \frac{(l_{j+1})^2}{2}, \forall 1 \leq j \leq I_i - 1.
\]

For the last sub-interval of the \( I_i \)th interval, the cost incurred by the 3rd Max-age user under the OPT policy is lower bounded by \( \sum_{k=1}^{l_{I_i}} 1 \) (since at the \( I_i \)th sub-interval sub-residue length does not exist). Hence the cost incurred by the 2nd Max-age and the 3rd Max-age user under the OPT at the \( I_i \)th sub-interval is lower bounded by

\[
\sum_{k=1}^{l_{I_i}} k + \sum_{k=1}^{l_{I_i}} 1 \geq \frac{(l_{I_i})^2}{2}
\]

Finally, summing up the cost over all sub-intervals in the \( t \)th interval, we get the following lower bound to the cost incurred by the 2nd Max-age and the 3rd Max-age user under the OPT policy:

\[
\frac{(l_{I_i})^2}{2} + \sum_{j=1}^{I_i-1} \left( \frac{(l_j)^2}{2} + \frac{(l_{j+1})^2}{2} \right)
\]

where \( l_j \) is the sub-residue length of the last sub-interval of the \( t \)th interval and \( l_{I_i} \) is the length of the last sub-interval of the \( t \)th interval.

There are three scenarios depending on the values \( m \)th residue length \( \forall m \in \{2,3,\ldots\} \) i.e. \( l_m \) can take,

- Case 1: \( l_m \leq I_{m-1} \).
Case 1: Consider the first scenario where \( l_m \leq l_{m-1} \) for all \( m \in \{2,3,\ldots\} \). Now consider the Max-age user of \((i+1)\)th interval. The MA-CSIT policy serves the Max-age user \( l_{i+1} \) time slots before the beginning of the \((i+1)\)th interval \( l_{i+1} \) slot. The OPT policy can serve the Max-age user twice after \( l_{i+1} \) time slot. Since \( l_{i+1} \leq l_i \), the OPT policy can serve the Max-age user once at the beginning of \( l_i \) sub-interval and next at the beginning of \((i+1)\)th interval. So, the \( l_{i+1} \) time slots can be divided into two parts. The first part refers to the sub-residue length of the last sub-interval \( l_i \) and the next one refers to the length of final sub-interval \( l_{i+1} \).

Hence we have

\[
l'_i + l'_i = l_{i+1}
\]

Let \( a_i \) denotes the first part of \( l_i \) and \( b_i \) refers to the second part. So for the above case we have

\[
a_{i+1} = l'_i
\]
\[
b_{i+1} = l'_i
\]

Hence the lower bound of the OPT policy at Eq. \( (20) \) can be rewritten as

\[
\frac{b_i^2}{2} + \sum_{j=1}^{J-2} \left( \frac{l'_j}{2} + \frac{(l'_j+1)^2}{2} \right) + \sum_{j=1}^{J-1} \frac{a_i a_{i+1} + b_{i+1} b_{i+1}}{2}
\]

Since \( a_{i+1} = l'_i \) and \( b_{i+1} = l'_i \), we can rewrite Eqn. \( (17) \) as:

\[
C_{\text{MA-CSIT}}(l_i) \leq C_{\text{OPT}}(l_i) + l_i l_i + \sum_{j=1}^{J-1} (l'_j l'_j) + a_{i+1} b_{i+1}
\]

Summing the costs over all intervals from Eq. \( (25) \) and using the lower bound of the OPT policy for the Max-age user of Eq. \( (18) \) and the lower bound for the 2nd Max-age and the 3rd Max-age user of Eq. \( (24) \) we get the following bound:

\[
\frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 1 + \frac{\sum_i (l_i l_i + \sum_{j=1}^{J-1} (l'_j l'_j) + a_{i+1} b_{i+1})}{\sum_i (l_i^2 + \frac{b_i^2}{2} + \sum_{j=1}^{J-2} (\frac{l'_j}{2} + \frac{(l'_j+1)^2}{2}) + \frac{a_i a_{i+1} + b_{i+1} b_{i+1}}{2})}
\]

Using the AM-GM inequality, we have \( l_i l_i \leq \frac{l_i^2}{2} + \frac{l_i^2}{2} \),

\[
\sum_{j=1}^{J-1} (l'_j l'_j) \leq \sum_{j=1}^{J-1} \left( \frac{(l'_j)^2}{2} + \frac{(l'_j)^2}{2} \right) \quad \text{and} \quad a_{i+1} b_{i+1} \leq \frac{a_i^2}{2} + \frac{b_i^2}{2}.
\]

Hence, from the above, we get

\[
\frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 1 + \frac{\sum_i (\frac{l_i^2}{2} + \frac{l_i^2}{2} + \sum_{j=1}^{J-1} (\frac{(l'_j)^2}{2} + \frac{(l'_j)^2}{2}) + \frac{a_i^2}{2} + \frac{b_i^2}{2})}{\sum_i (\frac{l_i^2}{2} + \frac{l_i^2}{2} + \sum_{j=1}^{J-2} (\frac{l'_j}{2} + \frac{(l'_j+1)^2}{2}) + \frac{a_i^2}{2} + \frac{b_i^2}{2})}
\]

Combining above equations we get

\[
\sum_i C_{\text{MA-CSIT}}(l_i) \leq 2 + \sum_i l_i \leq 2 + \frac{\sum_i (l_i^2)}{\sum_i (l_i^2 + l_{i+1}^2 + a_{i+1}^2)}
\]

Lower bounding the sub-interval lengths and the sub-residue lengths by zero, from the above, we have

\[
\frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 2 + \frac{\sum_i (l_i^2)}{\sum_i (l_i^2 + l_{i+1}^2 + a_{i+1}^2)}
\]

Since, \( a_i + b_i = l_i \), using the Cauchy-Schwartz inequality, we have \( a_i^2 + b_i^2 \geq l_i^2 / 2, \forall i \). Hence, the RHS of the above equation can be further upper bounded as below:

\[
\sum_i C_{\text{MA-CSIT}}(l_i) \leq 2 + \frac{\sum_i (l_i^2)}{\sum_i (l_i^2 + l_{i+1}^2 + a_{i+1}^2)}
\]

We have \( l_i \leq l_{i-1} \). Note that the RHS of Eqn. \( (30) \) is monotonically increasing for \( l_i \geq 0 \). Hence, we can upper bound the RHS of equation \( (30) \) by substituting \( l_i = l_{i-1} \). Therefore, we get

\[
\frac{\sum_i C_{\text{MA-CSIT}}(l_i)}{\sum_i C_{\text{OPT}}(l_i)} \leq 2 + \frac{\sum_i (l_i^2)}{\sum_i (l_i^2 + l_{i+1}^2)} \leq \frac{8}{3}
\]

Please see the Appendix section for the proof of Case 2 and Case 3. Hence, for all values of \( l_i \), we get \( \frac{\sum C_{\text{MA-CSIT}}(l_i)}{\sum C_{\text{OPT}}(l_i)} \leq \frac{8}{3} \) which implies \( \eta^{\text{MA-CSIT}} \leq \frac{8}{3} \).

IV. SIMULATION RESULTS

In this section we provide two particular channel configurations for 2 users and 3 users scenario to show the tightness of the bound provided in the \( \text{III-A} \) and \( \text{III-B} \) sections.

A. \( N = 2 \) users case

Consider the following channel state sequence for 2 users where the whole sequence is divided into intervals of fixed length \( \Delta \) where \( \Delta \) is even. At the beginning of every interval the channel corresponding to the user 1 is \text{Good} and the other
channel is **Bad**. For the next $\frac{3}{2} - 2$ slots both channels remain **Bad**. Next, at the $\frac{3}{2}^{\text{th}}$ slot both the channels become **Good**. After that, at the $(\frac{3}{2} + 1)^{\text{th}}$ slot, the channel corresponding to user 2 remains **Good** but other channel becomes **Bad**. For the next $\frac{3}{2} - 2$ slots both channels remain **Bad** and finally at the $\Delta^{\text{th}}$ slot both channels become **Good**. In Fig. 5 the AoI cost ratio between the MA-CSIT and the OPT policy for this particular channel state configuration has been plotted. It can be seen as interval length grows the cost ratio approaches 2, while in section III-A, we showed that for 2 user case the competitive ratio for the MA-CSIT policy is upper bounded by 2.

### B. $N = 3$ users case

In this case, we consider the interval length $\Delta$ to be multiple of 6. Here we mention at which time slot the channels corresponding to the users become **Good**. At the first time slot of the interval the channels corresponding to user 1 and 2 are only **Good**. For 2$^{\text{nd}}$ and 3$^{\text{rd}}$ time slots the channels corresponding user 1 and user 3 remain **Good** respectively. At the $(\frac{3}{2})^{\text{th}}$ time slot, the channels corresponding to user 1 and user 3 become **Good** and at the next time slot, the channel corresponding to the user 1 only remains **Good**. After that, at the $(\frac{3}{2} + 1)^{\text{th}}$ slot, the channels corresponding to user 2 and user 3 become **Good**. At next two time slots i.e. $(\frac{3}{2} + 2)^{\text{th}}$ and $(\frac{3}{2} + 3)^{\text{th}}$ slots the channels corresponding to user 2 and user 1 remain **Good** respectively. Next at the $\Delta^{\text{th}}$ time slot the channels corresponding to user 1 and user 2 become **Good** and at the next time slot, the channel corresponding to user 2 only remains **Good**. After that at $(\frac{3}{2} + 1)^{\text{th}}$ slot, the channels corresponding to user 1 and 3 become **Good**. For the next two time slots i.e. $(\frac{3}{2} + 2)^{\text{th}}$ and $(\frac{3}{2} + 3)^{\text{th}}$ slots the channels corresponding to user 3 and user 2 remain **Good** respectively. Next at $\frac{3}{2}\Delta^{\text{th}}$ time slot, the channels corresponding to user 2 and user 3 become **Good** and at the next time slot, the channel corresponding to user 3 only remains **Good**. In all other time slots the users which are not mentioned, the channels corresponding to those users remain **Bad**. For this particular scenario the AoI cost ratio between the MA-CSIT and the OPT policy has been plotted in Fig. 6. As $\Delta$ grows, the cost ratio approaches 2.25, while in section III-B, we showed that for 3 user case the competitive ratio for the MA-CSIT policy is upper bounded by 2.67.

### V. COMPARISON BETWEEN THE MA-CSIT AND THE MAX AGE POLICY

In this section we provide numerical results to show the advantage of having CSIT. Through simulations we compare the performance of MA-CSIT policy and the Max-Age policy [6, 8] which does not have CSIT. In this case we consider the channel states corresponding to each user to be independent and identically distributed. Consider the channel corresponding to each user can be **Good** with a probability $p$. In Fig. 7, Fig. 8, and Fig. 9 the time averaged AoI cost ($\text{AoI}_{\text{avg}}(T)$) for MA-CSIT policy and Max Age policy when $p = 0.5$, $p = 0.3$ and $p = 0.1$ have been plotted respectively. In Fig. 10 the ratio between the average AoI cost of Max Age policy and that of MA-CSIT policy for these three cases has been shown. From

VI. CONCLUSION

The paper investigates the fundamental limits of Age-of-Information for static users over adversarial environments when the scheduling policy is assumed to know the CSIT at the current slot. Theoretically we provide upper bound on the competitive ratio when the number of users is either 2 or 3. Through simulations, we showed that the greedy scheduling policy performs substantially better over adversarial setting when the policy is equipped with the channel state information at the current slot. Finding an upper bound on the competitive ratio for arbitrary number of users is an interesting open problem.

VII. ACKNOWLEDGEMENT

This work is partially supported by the grant IND-417880 from Qualcomm, USA and a research grant from the Govt. of India for the potential Center-of-Excellence Intelligent Networks under the IoE initiative. The computational results reported in this work were performed on the AQUA Cluster at the High Performance Computing Environment of IIT Madras.

VIII. APPENDIX

Case 2: $I_{m-2} + I_{m-1} > I_m > I_{m-1}$: In this case, before the $i$-th interval the last time slot at which the MA-CSIT policy can serve the Max-age user of $i$-th interval would lie somewhere at the $(i-2)$-th interval. At that time slot that user has the least age under the MA-CSIT policy. We denote that time slot as $T_i^j$ and the Max-age user of $i$-th interval as $u_{i_{max}}^j$. Next we need to determine the time slots where the OPT serves $u_{i_{max}}^j$ but the MA-CSIT does not.

- After $T_i^j$ time slot suppose, the OPT serves $u_{i_{max}}^j$ at some time slot at $(i-2)$-th interval but the MA-CSIT does not. This is only possible when the 2nd Max-age user and $u_{i_{max}}^j$ get Good channels. Since at the $(i-2)$-th interval, $u_{i_{max}}^j$ has the least age under the MA-CSIT policy, the MA-CSIT serves the 2nd Max-age user. Hence at that time slot $u_{i_{max}}^j$ becomes the 2nd Max-age user and at the $(i-1)$-th interval it will become the Max-age user. But it is not possible, as $u_{i_{max}}^j$ is the Max-age user of $i$-th interval and same user cannot become Max-age user at two consecutive intervals.

- Another possible scenario is after $T_i^j$ the 2nd Max-age user at the $(i-2)$-th interval gets Bad channels constantly and at the beginning of $(i-1)$-th interval the channels corresponding to both $u_{i_{max}}^j$ and the 2nd Max-age user become Good and the OPT serves $u_{i_{max}}^j$ instead of serving the 2nd Max-age user. In this scenario the MA-CSIT serves the Max-age user and the 2nd Max-age user becomes the Max-age user of the $(i-1)$-th interval i.e. $u_{i-1}$. But in this case the OPT policy can server $u_{i_{max}}^j$ at max once after the user gets served by the MA-CSIT policy which implies

$$a_{i-1} = t_{j_{i-1}}^{i-1} = I_{i-1}$$ (32)

At $T_i^j$ time slot the OPT policy can serve either 2nd Max-age user or the $u_{i_{max}}^j$. But if the OPT policy serves the $u_{i_{max}}^j$, then for the rest of the time slots of $(i-2)$-th interval and entire $(i-1)$-th interval the cost difference for that user under the OPT and the MA-CSIT policy remains zero. Suppose the OPT policy serves the 2nd Max-age user. Since after $T_i^j$ time slot, both $u_{i_{max}}^j$ and 2nd Max-age user get Bad channels constantly and $t_{j_{i-1}}^{i-1} < t_{j_{i-1}}^{i-1}$, the cost difference between the MA-CSIT and the OPT policy for the users other than the Max-age user for rest of the $(i-2)$-th interval

$$t_{j_{i-1}}^{i-1} - t_{j_{i-1}}^{i-1} - t_{j_{i-1}}^{i-1} < 0$$ (33)

Hence the cost difference between the MA-CSIT policy and the OPT policy at $(i-2)$-th interval is

$$C_{MA-CSIT}(I_{i-2}) - C_{OPT}(I_{i-2}) \leq \frac{I_{j_{i-1}}^{i-2}}{2} + \frac{I_{j_{i-1}}^{i-2}}{2} + \sum_{j=1}^{I_{j_{i-1}}^{i-1}} \frac{(I_{j_{i-1}}^{i-2})^2}{2} + \frac{(I_{j_{i-1}}^{i-1})^2}{2}$$ (34)

For this particular case at the $(i-1)$-th interval there will not be any sub-interval because $u_{i_{max}}^j$ can not get Good channel at the $(i-1)$-th interval, otherwise the MA-CSIT policy will serve $u_{i_{max}}^j$ immediately and this will contradict the assumption $I_i > I_{i-1}$. Thus, for $(i-1)$-th interval, we have

$$\sum_{j=1}^{I_{j_{i-1}}^{i-1}} \left( \frac{(I_{j_{i-1}}^{i-1})^2}{2} + \frac{(I_{j_{i-1}}^{i-1})^2}{2} \right) = 0$$ (35)

Since the OPT policy serves the $u_{i_{max}}^j$, at the beginning of $(i-1)$-th interval we have

$$b_i = I_{i-1}$$ (36)

Hence at $(i-1)$-th interval the cost difference between the MA-CSIT policy and the OPT policy is

$$C_{MA-CSIT}(I_{i-1}) - C_{OPT} \leq I_{i-1}I_{i-1} + a_i b_i$$ (37)

Since the OPT policy did not serve the 2nd Max-age user at the beginning of $(i-1)$-th interval the cost of $u_{i_{max}}^j$ under OPT policy is lower bounded by $\sum_{j=1}^{I_{j_{i-1}}^{i-1}} k \geq \frac{(l_i + d_i - 1)^2}{2}$.

Now consider, $N_1 = \sum_{j} I_{k \neq i, i-1} (l_i^2 + I_{j_{i-1}}^{i-1})^2 + \sum_{j=1}^{I_{j_{i-1}}^{i-1}} (I_{j_{i-1}}^{i-1})^2 + \frac{a_{i-1}^2}{2} + \frac{b_{i-1}^2}{2}$, $N_2 = \frac{I_{j_{i-1}}^{i-1}}{2} + \frac{I_{j_{i-1}}^{i-1}}{2} + \sum_{j=1}^{I_{j_{i-1}}^{i-1}} (I_{j_{i-1}}^{i-1})^2 + \frac{a_{i-1}^2}{2} + \frac{b_{i-1}^2}{2}$ and $N_3 = l_i - I_{i-1} + a_i b_i$. Also let $D_1 = \sum_{j=1}^{I_{j_{i-1}}^{i-1}} (l_i^2 + I_{j_{i-1}}^{i-1})^2 + \sum_{j=1}^{I_{j_{i-1}}^{i-1}} (I_{j_{i-1}}^{i-1})^2 + \frac{a_{i-1}^2}{2} + \frac{b_{i-1}^2}{2}$, $D_2 = \frac{I_{j_{i-1}}^{i-1}}{2} + \sum_{j=1}^{I_{j_{i-1}}^{i-1}} (I_{j_{i-1}}^{i-1})^2 + \frac{a_{i-1}^2}{2} + \frac{b_{i-1}^2}{2}$ and $D_3 = l_i + l_i m + \sum_{m=1}^{I_{j_{i-1}}^{i-1}} m + \sum_{m=1}^{I_{j_{i-1}}^{i-1}} m$. In the expression of $D_2$ the first summation indicates the lower bound on the cost incurred by $u_{i_{max}}^j$ under the OPT policy since it got served by the OPT policy for the last time before $(i-1)$-th interval. The rest two summations refer to the lower bound of the cost incurred by $u_{i_{max}}^j$ under the OPT policy since it got served by the MA-CSIT policy before $p_i$-th interval.

$$\sum_{i} C_{MA-CSIT}(I_i) \leq \sum_{i} C_{OPT}(I_i) \leq 1 + \frac{N_1 + N_2 + N_3}{D_1 + D_2 + D_3}$$ (38)

Since $b_i = I_{i-1}$ and $l_i \geq I_{i-1}$, simplifying above equations we get

$$\sum_{i} C_{MA-CSIT}(I_i) \leq 2 + \sum_{i} C_{OPT}(I_i) \leq 2 + \sum_{i} I_{k \neq i, i-1} (l_i^2 + I_{j_{i-1}}^{i-1})^2 + \frac{a_{i-1}^2}{2} + \frac{b_{i-1}^2}{2}$$ (39)
Hence we have
\[
\frac{\sum_i C_{\text{MA-CSIT}}(I_i)}{\sum_i C_{\text{OPT}}(I_i)} \leq 2 + \frac{\sum_k I_{(k \neq i)} I_k^2}{\sum_k I_{(k \neq i, j-1)} (I_k^2 + a_{k+1}^2 + b_{k+1}^2) + 2I_{j-1}^2} \leq \frac{8}{3}.
\]

**Case 3:** When \( I_i \geq I_{i-1} + I_{i-2} \), it is easy to check that for \( u_{\text{max}} \) cost under OPT will be always greater than the cost under MA-CSIT policy. Hence \( \frac{\sum_i C_{\text{MA-CSIT}}(I_i)}{\sum_i C_{\text{OPT}}(I_i)} \) is upper bounded by \( \frac{8}{3} \).
